OVERVIEW OF HEMOSTASIS

In response to vascular injury, hemorrhage is mitigated by an appropriately functioning hemostatic system. The hemostatic system relies on coagulation enzymes, platelets, and endothelial cells to form a blood clot, and coagulation inhibitors and fibrinolysis prevent unobstructed blood flow after clot formation. Any substance that disrupts the finely tuned balance of clot formation and fibrinolysis can result in hemorrhage, thrombosis, or both. Particularly in surgery, intraoperative and postoperative bleeding or thrombosis can occur secondary to technical challenges or from acquired or inherited defects in the hemostatic system. In this chapter, the original "coagulation cascade" will be reviewed, followed by the more refined and nuanced cell-based model. Subsequently, the most common inherited and acquired defects that result in bleeding or thrombosis in surgery will be presented, followed by common screening tools to determine hemostatic defects and common medical management or surgical interventions.

Activation of the Hemostatic System

In the mid-20th century, the original and renowned coagulation cascade proposed that coagulation could be triggered by one of two independent pathways, the *intrinsic* and *extrinsic* pathways. The *extrinsic pathway* is initiated when endothelial damage exposes plasma to tissue factor (TF), a subendothelial transmembrane glycoprotein that is abundantly expressed in adventitial tissues, such as fibroblast and vascular smooth muscle cells (VSMC).[1] The extrinsic pathway is complete when TF activates factor VII (FVIIa) and creates the TF:FVIIa complex. The *intrinsic pathway* was first described when clotting factors normally present in plasma were activated by artificial surfaces in vitro.[1] Subsequently, activated clotting factors activated downstream factors via limited proteolysis, which initiated an amplification cascade that proceeded in a stepwise manner. Although through different processes, the *extrinsic* and *intrinsic* pathways converged to activate the initiator of the final common pathway, factor X (FX). The result is the generation of the terminal procoagulant protease, thrombin, also known as *activated factor II* (FIIa), and the formation of a cross-linked fibrin clot (Fig. 100.1).

Although the coagulation cascade has proved to be useful in our understanding of coagulation and clinical interpretation of abnormal prothrombin time (PT) and activated partial thromboplastin time (PTT), in vivo evidence has shown that the distinct *extrinsic* and *intrinsic pathways* operate as a single integrated pathway during normal hemostasis. To date, the accepted model, known as the *cell-based model* of coagulation, emphasizes overlapping interactions of coagulation proteins and cell membranes.[2] The overlapping phases described in this model include *initiation, amplification,* and *propagation* (Fig. 100.2).

The *initiation phase* of hemostasis occurs when endothelial injury exposes subendothelial TF to circulating plasma clotting FVII (see Fig. 100.2A). This activates FVII and creates the TF:FVIIa *extrinsic tenase complex,* which is formed on the membranes of TF-expressing cells (fibroblast and VSMC). TF:FVIIa then activates circulating zymogen FX and factor IX (FIX) via enzymatic cleavage. FIX is found in the subendothelial space bound to type IV collagen and in plasma, where it exists in a dynamic equilibrium.[3] Reversibly bound and activated FX (FXa) then combines with activated cofactor V (FVa) on the surface of negatively charged cell membranes in the presence of calcium ions to form the *prothrombinase complex.*[4] This complex converts prothrombin (factor II) to thrombin (FIIa) and is responsible for the trace amounts of thrombin that trigger coagulation.

As the *initiation phase* of coagulation is occurring, platelets begin to aggregate and activate at the site of injury by binding to endothelial-derived von Willebrand factor (vWF) and subendothelial collagen fibers via receptors glycoprotein (GP)Ib and GPIa/IIa or GPVI, respectively. Together, the stimulation of platelets with subendothelial collagen fibers and thrombin generated from the *prothrombase complex* enables platelet structural alterations.[2,5] One feature of this alteration is the outer membrane of the

platelet becoming net negatively charged. Platelet structural change then initiates the *amplification phase* as the negatively charged membrane surface provides the platform for the activation of coagulation factors and creation of enzyme complexes (see Fig. 100.2B). Some of the plasma factors that negatively charged platelets activate are factor XII (FXII) and prekallikrien, via limited proteolysis.[1] FXII, prekallikrien and high-molecular-weight kininogen are responsible for propagating the *contact pathway,* initially referred to as the *intrinsic pathway.*[5] In the *contact pathway,* activated FXII (FXIIa) activates factor XI (FXIa), which in turn activates FIX (FIXa). While this is occurring, thrombin generated on TF-expressing cells (the thrombin spark) is further catalyzing the activation of FIX, FVIII, and FV. FIXa generated from the TF:FVIIa complex in the *initiation phase* and from the thrombin spark complexes with FVIIIa to form the *intrinsic tenase complex.* The *intrinsic tenase complex* then greatly accelerates FXa generation and therefore thrombin generation. As a reminder, thrombin generated from FXa is possible through the formation of the *prothrombinase complex* (FXa, FVa, and prothrombin). The overall net effect is a positive feedback loop amplification.

The *propagation phase* of coagulation follows the amplification phase in which accumulated enzyme complexes (*intrinsic tenase complex* and *prothrombinase*) on the platelet surface support large-scale thrombin generation (see Fig. 100.2B). As thrombin is being generated, fibrinogen binds to cell membrane receptor GPIIb/IIIa on activated platelets, serving as a molecular link to mediate platelet aggregation.[6] Generated thrombin then cleaves the soluble glycoprotein fibrinogen to insoluble fibrin and activates FXIII to FXIIIa. FXIIIa covalently links fibrin polymers, which gives the platelet clot shape, strength, flexibility, and stability.

Although platelets are demonstrated to be the cornerstone of thrombus, their role in hemostasis extends even further. To begin, platelets are small (~2–4 μm), short-lived (~8–10 days), anucleated cell fragments derived from the megakaryocyte lineage.[7] The platelet surface is covered by a layer of glycolipid and glycoprotein molecules containing receptors for various soluble and fixed ligands. These ligands mediate adhesion, signaling, activation, spreading, and aggregation. However, the multifaceted function of platelets comes from the release of numerous intracytoplasmic granules (alpha, dense, and lysosomal) after platelet activation. More than 300 proteins from their intracytoplasmic granules are released in response to different agonists at different degrees of stimulation.[5] Activation of platelets can occur via thrombin stimulation (as previously described) or by adenosine diphosphate (ADP), adenosine triphosphate (ATP), and prostanoids such as thromboxane A2 (a mediator of vasoconstriction). Once activated, platelets undergo shape change (creating a negatively charged surface to provide the platform for the activation of clotting factors), degranulation, aggregation, and increased sensitivity to other agonists. Some factors released by platelets include platelet activators (platelet-activating factor, thromboxane A2), growth and angiogenic factors, cytokines and chemokines, adhesion molecules, coagulation factors (vWF, FV, FXIII, high-molecular-weight kininogen, fibrinogen), anticoagulation factors (TF pathway inhibitor, protein S), fibrinolytic factors (plasmin, plasminogen), antifibrinolytic factors (α_2-antiplasmin, thrombin activatable fibrinolysis inhibitor, plasminogen activator inhibitor-1 [PAI-1]), ADP, ATP, and other molecules.[7] In sum, platelets play a key role not only in primary hemostasis but also in thrombosis and even inflammation.

Endogenous Inhibitors of the Hemostatic System

In an appropriately functioning coagulation system, inappropriate activation is regulated at various stages by inhibitors (Fig. 100.3). In *the initiation phase* of coagulation, tissue factor plasma inhibitor (TFPI) is bound to glycosaminoglycans on uninjured endothelium and prevents excessive fibrin clot formation down or upstream of injury by inhibiting TF:FVIIa as well as directly inhibiting FXa activity.[1,2] TFPI, a serine protease inhibitor, is also released by activated platelets. When TFPI binds to cofactor protein S, a circulating and platelet-stored vitamin K–dependent protein, TFPI's anti-FXa activity is enhanced.[8] Protein S is also known to be an important cofactor in inhibition

FIGURE 100.2 (A–B) Cell-based model of coagulation. In the cell-based model, there is an *initiation phase, amplification phase,* and *propagation phase.* (A) In the initiation phase, vascular injury results in the TF:FVIIa complex, also known as the *extrinsic tenase complex,* which activates FV, FIX, and FX and subsequently generates the *prothrombinase complex* (FXa:FVa). The *prothrombinase complex* then generates the thrombin spark. (B) The thrombin spark initiates the activation of platelets and other clotting factors, including FVa, FVIIIa, and FIXa. Once platelets are activated, amplification ensues as platelets behave as a platform for the activation of clotting factors. The result is the formation of the *intrinsic tenase complex,* which greatly accelerates FXa generation and therefore thrombin via the *prothrombinase complex.* *Ca^{2+}* refers to the steps that require calcium. *Red cells* indicate endothelial cells *(EC); orange cells* indicate fibroblast/vascular smooth muscle cells. *GP,* Glycoprotein; *F,* factor; *TF,* tissue factor; *vWF,* von Willebrand factor.

during the *propagation phase* of coagulation. In this phase, protein S interacts with activated protein C. Protein C is a serine protease that is activated in response to thrombin binding to endothelial cofactor receptor thrombomodulin. Together, protein S and activated protein C inactivate FVa and FVIIIa, cofactors in the *prothrombinase* and *intrinsic complexes*, respectively.

Antithrombin is another serine protease inhibitor synthesized in the liver that regulates the *intrinsic and extrinsic complexes*. The liver synthesizes two isoforms of antithrombin: α and β. The α-isoform is more abundant (90%–95%) but demonstrates lower affinity for heparin than the β-isoform, therefore making the β-isoform more important for regulating anticoagulation.[9] Antithrombin's anticoagulant activity is activated once it binds to therapeutic heparins, heparan sulfate proteoglycans, and glycosaminoglycans on vascular endothelial cells.[10] The activated antithrombin then undergoes a conformational change that creates a reactive loop site and covalent bonds between serpin and proteases, which leads to the irreversible binding of antithrombin-thrombin and antithrombin-FX complexes (FXa and, to a lesser degree, FIXa, XIa, XIIa, tissue-type plasminogen activator [t-PA], urokinase, trypsin, plasmin, and kallikrein).[9] The irreversibly bound factors are then excreted via the kidneys.

Although there are several inhibitors to the hemostatic system, the cornerstone for the removal of fibrin blood clots is via the fibrinolytic system. In this system, plasmin acts as the active fibrinolytic protease. Plasmin is derived from plasminogen. Plasminogen is a glycoprotein that circulates in blood and is activated to form plasmin on a needs-only basis by t-PA or urokinase-type plasminogen activator (u-PA).[11] Activation occurs when plasminogen binds fibrin, unfolding plasminogen and exposing

FIGURE 100.3 (A–B) Inhibitors of coagulation. (A) Tissue factor plasma inhibitor *(TFPI)* inhibits the TF:FVIIa complex as well as directly inhibits FXa. Its inhibitory effect is enhanced when cofactor protein S is bound *(blue diamond).* (B) Protein C is activated by thrombin binding to endothelial cofactor receptor thrombomodulin. Activated protein C then binds to cofactor protein S, and together, they inhibit cofactors FVa and FVIIIa. Antithrombin III is then activated by binding to heparan sulfate proteoglycans on vascular endothelial cells. Antithrombin III's role is preferentially to inhibit the common pathway by inhibiting FXa and inhibiting the intrinsic tenase complex by inhibiting FIXa. *F,* Factor; *TF,* tissue factor; *vWF,* von Willebrand factor.

plasminogen's cleavage sites to the cellularly secreted serine proteases t-PA or u-PA.[11] The activation to plasmin then causes degradation of FV and FVIII (disrupting the *prothrombinase complex* and *intrinsic tenase complex*) while cleaving cross-linked fibrin, dissolving the fibrin clot. Given plasmin's role in fibrinolysis, excessive plasmin formation can lead to excessive bleeding. In normal physiologic conditions, plasmin inhibition is controlled by t-PA and u-PA inhibitors, PAI-1, PAI-2, α_2-antiplasmin, thrombin activatable fibrinolysis inhibitor, α_2-macroglobulin, or C1 inhibitor.

DISORDERS OF HEMOSTASIS

Inherited Disorders of Hemostasis

Von Willebrand Disease (Types I-III)

Von Willebrand disease (vWD) is the most common inherited disorder of hemostasis, with an estimated population prevalence of 0.6% to 1.3%.[12] The underlying etiology can be either a quantitative deficiency of vWF or a functional deficiency of vWF, depending on the type of vWD. vWF is a complex polypeptide with two primary functions for hemostasis. First, vWF activates platelets, as previously described. Additionally, vWF binds FVIII and prevents its degradation by proteases, thus stabilizing FVIII and prolonging FVIII half-life while circulating in plasma.[13] Thrombin later cleaves the vWF-FVIII complexes so that FVIIIa can contribute to the common pathway of the coagulation cascade. Without vWF, there would be decreased availability of FVIII for hemostasis (Table 100.1).

There are three main types of vWD, which follow an autosomal inheritance pattern. Type I vWD is the most common type, estimated to be 80% of vWD cases, with the mildest clinical manifestations.[12] Type I vWD is caused by a quantitative deficiency of circulating vWF with otherwise functional vWF. In comparison, type II vWD is caused by a dysfunctional vWF. The various subtypes of type II vWD are distinguished by the specific

TABLE 100.1 **Disorders of Hemostasis**

			UNDERLYING PATHOPHYSIOLOGY	MANAGEMENT
Inherited Disorders		Von Willebrand disease	Quantitative deficiency of vWF (type 1), functional defect (type 2), or total absence of vWF (type 3)	DDAVP ± vWF-FVIII concentrates
		Hemophilias	Deficiency of FVIII (hemophilia A), FIX (hemophilia B), or FXIII (hemophilia C)	Coagulation factor concentrate replacement therapy Emicizumab therapy for hemophilia A
Acquired Disorders	Coagulation Disorders	Trauma-induced coagulopathy	Loss of coagulation factors, impaired platelets, inhibition of calcium cofactor, acidosis	1:1:1 transfusion protocol with electrolyte repletion and stabilization of injuries
		Disseminated Intravascular coagulation (DIC)	Dysregulation of thrombotic processes followed by consumption of coagulation factors and platelets	Treatment of underlying cause (e.g., sepsis, obstetrical complication)
		Liver dysfunction	Decreased synthesis of platelets and coagulation factors; increased fibrinolysis	Supportive care; TEG-guided management of transfusions to balance hypercoagulable and hypocoagulable states
		Vitamin K deficiency	Lack of carboxylation and activation of vitamin K–dependent coagulation factors II, VII, IX, and X	Vitamin K supplementation (oral, intravenous, or intramuscular); PCC for immediate correction of factor deficiencies
		Bovine thrombin–induced coagulopathy	Cross-reactivity of antibodies to bovine FV (found in bovine thrombin preparations) with human FV	Platelets; avoidance of bovine thrombin in future procedures
	Platelet Disorders	Uremia	Reduced GPIa levels on platelets and decreased binding of GPIIb/IIIa to fibrinogen for platelet activation	Hemodialysis; DDAVP or cryoprecipitate can be considered for temporary improvement

functional issue, such as decreased platelet-binding activity or loss of high-molecular-weight vWF multimers. Type III vWD is the rarest and most severe type of the disease and is caused by the complete absence of vWF. Clinical manifestations include ecchymosis, epistaxis, gastrointestinal bleeding from angiodysplasia, menorrhagia, and hematomas. Bleeding after surgical or dental procedures is very common in patients with vWD, and prophylactic treatment should be considered to aid with hemostasis in patients undergoing procedures.

Hemophilia

Hemophilia is a group of rare X-linked inherited diseases that result in deficiency of coagulation factors. Given its inheritance pattern, a meta-analysis of international registries focusing on hemophilia prevalence in males was performed in 2019. The results demonstrated an overall prevalence of 17.1 cases of hemophilia A (HA) per 100,000 males and 3.8 cases of hemophilia B (HB) per 100,000 males.[14] Specifically, HA is a deficiency of FVIII, and HB is a deficiency of FIX. Hemophilia C (HC) is even less common than HA and HB and is an autosomal recessive disorder with a deficiency of FXI.[15] Deficiency of coagulation factors results in delayed hemostasis and prolonged bleeding. Severity of the disease is dependent on the patient's baseline levels of coagulation factors. Therefore, clinical manifestations range from prolonged bleeding from minor injury or dental procedures to spontaneous hemorrhage into muscles, joint spaces, or intracranially.

Hemophilias are diagnosed and monitored using coagulation tests such as PT. Mixing studies can be performed to assess whether the prolonged PT is corrected with the addition of normal plasma and coagulation factors to the patient's plasma sample. Patients receiving factor replacement therapy may develop neutralizing antibodies that reduce the therapeutic effect in hemophilia patients.[16] Further testing can be performed to assess the levels of antibodies to FVIII or FIX and to measure the functional effect of the inhibitors, which could help guide treatment.[17]

Although hemophilia is largely an inherited disease, acquired HA (AHA) is an autoimmune disease that can develop, primarily in elderly patients. AHA arises from spontaneous production of neutralizing antibodies to FVIII and carries a high risk of mortality.[18] The occurrence of AHA may be preceded by malignancy, other autoimmune conditions, or infections. Human FVIII is ineffective in AHA, so porcine or recombinant FVIII may be used to aid in hemostasis. Emicizumab is hypothesized to be effective in the setting of AHA; however, further clinical trials are needed to support the safety and efficacy of this drug in this patient population.[19]

Acquired Disorders of Hemostasis

Trauma-Induced Coagulopathy

Trauma-induced coagulopathy (TIC) typically involves multiple factors, such as hypovolemia, metabolic derangements, liver dysfunction, and hypothermia. Hemorrhage after trauma is a major cause of death worldwide, and identifying the underlying issues for each patient is critical to correct the coagulopathy.[20] There are two phases of TIC. The early phase is characterized by diffuse endothelial trauma leading to altered thrombin production, loss of coagulation factors by hemorrhage, and hyperfibrinolysis. The protein C system is also activated, resulting in diminished FV and FVIII as well as increased fibrinolysis resulting from inhibition of PAI-1.[21] Platelets are commonly dysfunctional in TIC, preventing successful primary hemostasis and clot formation. This phenomenon has been termed *platelet exhaustion* because platelet levels may be normal, but platelet function is impaired.[22] With resuscitation and transfusions, the coagulopathy can worsen as a result of the dilutional effect on coagulation factors and decreased levels of calcium as a coagulation cofactor from citrate-containing blood products. More recent investigations also demonstrate inflammatory and immunomodulatory components of TIC.[22] As the trauma patient progresses through the resuscitative and stabilization phases, they move toward a more hypercoagulable state that resembles a consumptive coagulopathy state, such as in disseminated intravascular coagulation (DIC).[23] Early thromboprophylaxis is initiated in the late phase once hemostasis and supportive measures are in place.

Disseminated Intravascular Coagulation

DIC is a complex, systemic process that involves disorders of both coagulation and fibrinolysis and is associated with high (31%–86%) morbidity and mortality rates.[24] Most commonly, DIC is caused by infection; however, other etiologies include malignancy, severe bleeding after trauma, and obstetrical complications such as placental abruption or amniotic fluid embolism.[23] In the early phase of DIC, there is increased TF expression that leads to increased activation of prothrombin and thrombin.[25] Furthermore, the normal anticoagulant processes involving inhibitors such as TFPI, antithrombin, and protein C are impaired.[26] Additionally, normal fibrinolysis processes are interrupted by elevated levels of PAI-1, the primary inhibitor of fibrinolysis.[27] PAI-1 is increased during acute inflammatory phases and released by activated platelets, producing a prothrombotic state in which platelet activation and fibrin formation are elevated, with limited regulation.

The later phase of DIC involves a state of "consumptive coagulopathy" in which the liver cannot synthesize enough coagulation factors to compensate for the number of factors that were activated and used during the prothrombotic phase.[24] In this phase, the patient is subject to both bleeding and thrombotic complications as a result of competing processes of coagulation and fibrinolysis.

A defining feature of DIC is the "loss of localized activation of coagulation."[23] As part of this systemic process, dysregulated platelet aggregation and fibrin formation in the microvasculature result in microthrombus formation that can lead to organ failure. Other symptoms include mucosal bleeding, petechiae, and purpura secondary to thrombocytopenia. There are various scoring systems based on laboratory testing and symptoms that intend to detect DIC in the earlier phase; however, their predictive value has not yet been validated.[24] Laboratory abnormalities seen in DIC include thrombocytopenia, prolonged coagulation time, and increased fibrin degradation products (e.g., D-dimer).[27] Ongoing studies of biomarkers for DIC are investigating the potential utility of antithrombin, protein C, D-dimer, PAI-1, and vWF.[26]

Management of DIC is centered on treatment of the underlying cause. Once stabilized from obstetrical complications, patients may resolve within hours, whereas sepsis-induced DIC frequently persists and progresses.[26] Sequelae of failure of various organs should be recognized and addressed. Often, replacement of coagulation factors or platelets is given to help with hemostasis. However, transfusion of these products can also be challenging in the later phase of DIC because transfusion of blood products may worsen the thrombotic burden.

Liver Dysfunction

Traditionally, patients with liver dysfunction were believed to be in a hypocoagulable state as a result of decreased synthesis of platelets and coagulation factors. Although this is true to some extent, more recent investigations suggest there is also a hypercoagulable component with hepatic dysfunction. As a result of diffuse endothelial damage, there are increased vWF and FVIII levels, leading to a higher risk of hypercoagulability.[28] Additionally, the liver is not able to synthesize normal levels of disintegrin and metalloproteinases that are responsible for the breakdown of vWF, further amplifying the prothrombotic effects of vWF. Fibrinolysis is also increased in hepatic dysfunction because FXIII synthesis is decreased and hepatic clearance of factors such as t-PA is diminished. Thus, hepatic dysfunction puts the patient in a balance between hypocoagulable and hypercoagulable states. Patients with end-stage liver disease are often at higher risk of deep venous thrombosis (DVT), portal venous thrombosis, and pulmonary embolism (PE) while also having an increased risk of excessive bleeding.

Standard laboratory testing may not accurately reflect the tenuous balance of coagulability in patients with end-stage liver disease. The PT, international normalized ratio (INR), and platelet levels are often abnormal with hepatic dysfunction. However, the American Gastroenterological Association best clinical practice guidelines for cirrhotic patients suggest that standard transfusion protocols based on INR levels are not supported by evidence, especially because excessive transfusions can lead to elevated portal pressures and volume overload.[29] Instead, recent studies suggest thromboelastography (TEG) as a better test to assess the overall hemostasis profile for patients with hepatic dysfunction because TEG-guided resuscitation versus standard laboratory tests led to reduced transfusions of platelets and fresh frozen plasma (FFP) without differences in postprocedural bleeding or complication rates (Fig. 100.1).[30,31] These findings suggest TEG may be a better test for patients with hepatic dysfunction because of its more comprehensive assessment of the phases of hemostasis.

Vitamin K Deficiency

Vitamin K is a fat-soluble vitamin that plays a role in multiple systems in the body, including bone development and cardiovascular disease. Vitamin K exists in different forms; vitamin K_1 is primarily found in leafy green plant sources, whereas vitamin K_2 is found in dietary sources such as fish, chicken, or dairy products and can also be biologically activated by gut flora of the distal small bowel and colon.[32] Vitamin K_2 has a longer half-life and a greater effect on vitamin K–dependent proteins compared with vitamin K_1. Notably, vitamin K serves as a cofactor to the enzyme gamma-glutamyl carboxylase, which adds carboxyl groups to various calcium-dependent proteins. Particularly in hemostasis, vitamin K helps activate the calcium-dependent proteins FII, FVII, FIX, and FX and proteins C and S[33]; therefore, vitamin K deficiency can prevent their normal functioning. Vitamin K deficiency can arise from inadequate dietary intake, malabsorption in the small bowel, and loss of storage sites in liver disease.[34] In preparation for surgery, individuals with vitamin K deficiency and prolonged PT or INR should be supplemented with oral or parental vitamin K. In the setting of acute bleeding with vitamin K deficiency, prothrombin complex concentrate (PCC) can also be administered to increase levels of vitamin K–dependent factors and improve hemostasis.

Vitamin K deficiency is also seen in the neonatal and postnatal periods as a result of certain medications given to the mothers during pregnancy, low placental transfer of vitamin K, low absorption in the newborn intestines, or low concentration of vitamin K in breast milk.[35] Therefore, the American Academy of Pediatrics recommends intramuscular administration of vitamin K to all newborn infants.[36] Additional redosing can be considered for infants who show signs of late-onset vitamin K–deficiency bleeding.

Uremia and Bleeding in End-Stage Renal Disease

Patients with end-stage renal disease (ESRD) have a higher tendency to bleed. This is attributed to not only lower levels of blood and coagulation factors resulting from anemia of chronic disease but also platelet dysfunction secondary to uremia.[34] In uremic patients, the cytoskeletal proteins are deficient, impairing platelet motility and adhesion.[37] Platelet activation is dependent on the binding of vWF to GPIb on platelets as well as the binding of fibrinogen to GPIIb/IIIa on platelets. Decreased levels of GPIb have been noted in patients with uremia, which may explain the impaired primary hemostasis for uremic patients.[37]

Additionally, toxins circulating in uremic plasma contribute to platelet dysfunction; however, the specific contributing components have not yet been identified. However, although the number of GPIIb/IIIa receptors is normal in uremia, their binding activity is diminished. The impaired binding of GPIIb/IIIa receptors is a reversible process that improves with dialysis.[38] Thus, although hemodialysis does not fully correct the platelet dysfunction, the clearance of potential toxins and reversal of abnormal GPIIb/IIIa binding to fibrinogen helps manage bleeding in patients with ESRD. Timing of hemodialysis sessions should be considered when scheduling patients with ESRD for surgery. Other adjuncts such as cryoprecipitate and desmopressin (DDAVP) may be considered to temporarily increase vWF, FVIII, or fibrinogen to overcome the platelet impairment.

Bovine Thrombin–Induced Coagulopathy

Bovine thrombin–induced coagulopathy is a rare disorder of hemostasis that has been described in various postoperative settings. The etiology is believed to be caused by development of antibodies to coagulation FV after prior exposure to topical bovine thrombin during surgery.[39] Thrombin is frequently used as a topical hemostatic agent in cardiovascular surgery, neurosurgery, and pediatric surgery. Different thrombin preparations exist, including bovine thrombin, plasma-derived human thrombin, and recombinant human thrombin. Although the thrombin is purified and processed, traces of bovine factors, such as FV, can remain.[40] Some patients may develop an immune response to these proteins during a second procedure, leading to development of antibodies to bovine FV. Cross-reactivity with human FV then results in destruction of the patient's own FV, leading to bleeding. Therefore, thrombin-induced coagulopathy is also referred to as *immune-mediated coagulopathy*.

Not all patients who develop antibodies to bovine thrombin preparations will develop bleeding complications; multiple exposures to bovine thrombin increase the risk of antibody development and the risk of bleeding complications.[41] Although rare, bovine thrombin–induced coagulopathy should be considered in the differential diagnosis of a patient with persistent postoperative bleeding that does not respond to surgical reexploration, blood products, or coagulation factor transfusions. If suspected, plasmapheresis or platelet transfusions have been suggested as management. Platelets contain FV that are released upon platelet activation. Platelet-derived FV is believed to be protected from anti-FV antibodies, as opposed to FV delivered from FFP.[40] Bovine thrombin should also be avoided in future procedures to prevent reexposures that could trigger antibody formation.

Iatrogenic Coagulopathies Secondary to Anticoagulant/Antiplatelet Use

There are a variety of medical conditions that require patients to be prescribed antiplatelet or anticoagulation therapy. The benefits of the therapeutic agent should be weighed against the risk of bleeding in each patient. For example, the annual incidence of bleeding while on warfarin is estimated to be 15% to 20%, with an annual life-threatening bleeding rate of 1% to 3%.[42] This highlights the need to understand the underlying mechanism of each medication and its reversal agent to rapidly correct the hypercoagulable state in an emergency. Tables 100.2 and 100.3 show the most commonly prescribed anticoagulation and antiplatelet drugs, along with their corresponding mechanisms of actions and reversal agents.[43]

Diagnosis

Testing

Initial assessment of coagulation status involves measuring the PT, PTT, INR, and thrombin time. The PT evaluates the extrinsic and common pathway of coagulation, whereas the PTT evaluates the intrinsic and common pathway. When prolonged, the PT and PTT suggest a deficiency in coagulation factor(s) or whether an inhibitor to coagulation factors is present.[44] The PT is useful in monitoring the efficacy of vitamin K antagonists, such as warfarin, because it involves measurement of vitamin K–dependent factors II, VII, IX, and X.[45] The INR is calculated using the PT value and is therefore also commonly used for monitoring vitamin K–antagonist levels. The PTT is useful in testing for inherited diseases of coagulation, such as hemophilia, because the PTT measures include factors VIII and IX. Additionally, PTT is used to monitor and titrate unfractionated heparin for inpatients receiving continuous anticoagulation infusions. Unfractionated heparin inhibits prothrombin and FX, both of which are measured by the PTT. The activated clotting time (ACT) is a point-of-care test that is commonly used during procedures such as vascular surgeries or cardiopulmonary bypass to titrate anticoagulant doses to reach a desired threshold.

Quantification of blood components, such as a complete blood count, is also useful to determine the presence of thrombocytopenia that could be contributing to lack of hemostasis. Notably, pseudothrombocytopenia occurs when platelets clump in the laboratory sample as a result of anticoagulants such as ethylenediaminetetraacetic acid (EDTA) or cold agglutinins, leading to a falsely low platelet count.[44] Performing the test in tubes with other anticoagulants or with the sample kept at a different temperature can confirm the presence or absence of thrombocytopenia.

Fibrinogen is critical for the formation of stable clots for hemostasis. Fibrinogen levels can be measured from plasma samples directly, whereas the functional status of fibrinogen can be assessed using viscoelastic testing, such as rotational thromboelastometry (ROTEM).[46] Plasmin later breaks down the clot into fibrin degradation products that can be quantified by various immunoassay tests. These fibrin and fibrinogen degradation products are of varying sizes and molecular masses. One such fibrin degradation product is the D-dimer complex, which consists of two "D domains" that are connected by a central "E domain."[47] D-dimer levels can be measured via immunoassays that detect the D-dimer motifs that arise from fibrin degradation by plasmin. Measuring fibrin and fibrinogen degradation products can be particularly helpful with consumptive disease pathologies such as DIC.[48]

Additional testing for vWD includes measurement of the vWF antigen level, the vWF-Ristocetin assay, and measurement of FVIII activity. Low levels of vWF suggest type I vWD or type III vWD. These two types can be distinguished by extremely low

TABLE 100.2 Common Anticoagulation Therapies

	MEDICATION	ROUTE	MECHANISM	HALF-LIFE	CLEARANCE	REVERSAL AGENT
Anticoagulant	Heparin	Parenteral	Binds to antithrombin, then binds to and inhibits prothrombin	30–90 min	Reticuloendothelial System	Protamine
	Low-molecular-weight heparin (LMWH)	Parenteral	Activates antithrombin complex, which then inactivates factor Xa and prothrombin	3–6 h	Renal	Protamine Andexanet alfa[a]
	Fondaparinux	Parenteral	Highly selective binding to antithrombin to inhibit factor Xa	17–21 h	Renal	Recombinant factor VII PCC
	Bivalirudin, argatroban	Parenteral	Direct thrombin inhibitor, typically used for HIT	Bivalirudin: 25 min Argatroban: 40-50 min	Bivalirudin: renal Argatroban: Hepatic	N/A
	Warfarin (Coumarin)	Enteral	Vitamin K antagonists that inhibit activation of vitamin K–dependent coagulation factors (II, VII, IX, and X)	∼35 h	Hepatic	Vitamin K therapy PCC or FFP
	Dabigatran (Pradaxa)	Enteral	Thrombin inhibitor	12–17 h	Renal	Idarucizumab (Praxbind)[b] Cryoprecipitate PCC
	DOACs (rivaroxaban [Xarelto], apixaban [Eliquis], edoxaban [Savaysa])	Enteral	Bind directly to factor Xa or prothrombin without first binding to antithrombin	Apixaban: 12 h Rivaroxaban: 5–13 h Edoxaban: 10–14 h	*Apixaban*: 25% renal, 75% feces *Rivaroxaban*: hepatic, renal, minimal fecal *Edoxaban:* renal, fecal, minimal hepatic	Andexanet alfa PCC

[a] Andexanet alfa is recombinant factor Xa.

[b] Idarucizumab (Praxbind) is a monoclonal antibody that binds dabigatran.

DOAC, Direct oral anticoagulation; *FFP,* fresh frozen plasma; *HIT,* heparin-induced thrombocytopenia; *N/A,* not applicable; *PCC,* prothrombin complex concentrate.

TABLE 100.3 Common Antiplatelet Therapies

	MEDICATION	MECHANISM	REVERSAL AGENT
Antiplatelet	Acetylsalicylic acid/ aspirin	Inhibits cyclooxygenase (COX)-1 → prevents generation of prostaglandin H2 and thromboxane A2 → impaired platelet activation and aggregation	No specific reversal agent • Stop aspirin 7–10 days before planned procedure • Consider platelet transfusion or DDAVP for acute bleeding
	Clopidogrel, ticagrelor, prasugrel, cangrelor	Thienopyridines that irreversibly block P2Y12 ADP receptors on platelets → preventing aggregation	No specific reversal agent • Stop clopidogrel 5 days before planned procedure • Consider platelet transfusion or DDAVP for acute bleeding
	Dipyridamole	Inhibits cAMP phosphodiesterase → increased cAMP levels within platelets and decreased thromboxane A2 activity → impaired platelet function	No specific reversal agent • Consider platelet transfusion or DDAVP for acute bleeding
	Cilostazol	Phosphodiesterase 3 inhibitor; similar mechanism to dipyridamole	No specific reversal agent • Consider platelet transfusion or DDAVP for acute bleeding
	Abciximab, eptifibatide, tirofiban	Inhibit GPIIb/IIIa receptors on platelets → platelets unable to bind fibrin and aggregate	No specific reversal agent • Consider platelet transfusion or DDAVP for acute bleeding

ADP, Adenosine diphosphate; *cAMP,* cyclic adenosine monophosphate; *DDVAP,* desmopressin.

levels of vWF antigen (<5 IU/dL) or by measuring the vWF propeptide, which is formed during the synthesis of vWF.[12] Type I vWD will have normal or slightly decreased vWF propeptide levels, whereas type III vWD will have absent or significantly decreased vWF propeptide levels. The vWF-Ristocetin assay evaluates the platelet-binding activity of vWF. Ristocetin is a cofactor that binds to vWF and platelets to trigger platelet aggregation.[49] Therefore, patients with vWD will have decreased platelet aggregation on the vWF-Ristocetin assay. Similarly, because vWF is an essential carrier for FVIII, patients with vWD will have decreased FVIII activity.

Rotational Thromboelastometry/Thromboelestography

TEG is a whole blood assay that evaluates all phases of hemostasis, including aggregation, clot strengthening, and fibrinolysis (Fig. 100.4). A sample is mixed with buffered sodium citrate and then placed into a cup in which there is a pin suspended in the center. The cup is oscillated around the pin, and the movement of the pin is recorded.[50,51] The TEG tracing is thus a reflection of the viscosity of blood as it progresses through hemostasis. A "rapid TEG" involves adding TF to the sample to accelerate the clotting process and provide results within 15 minutes, which can be particularly helpful in an acute setting.[50] The variables recorded in the TEG provide information on different factors that contribute to clot formation and degradation.

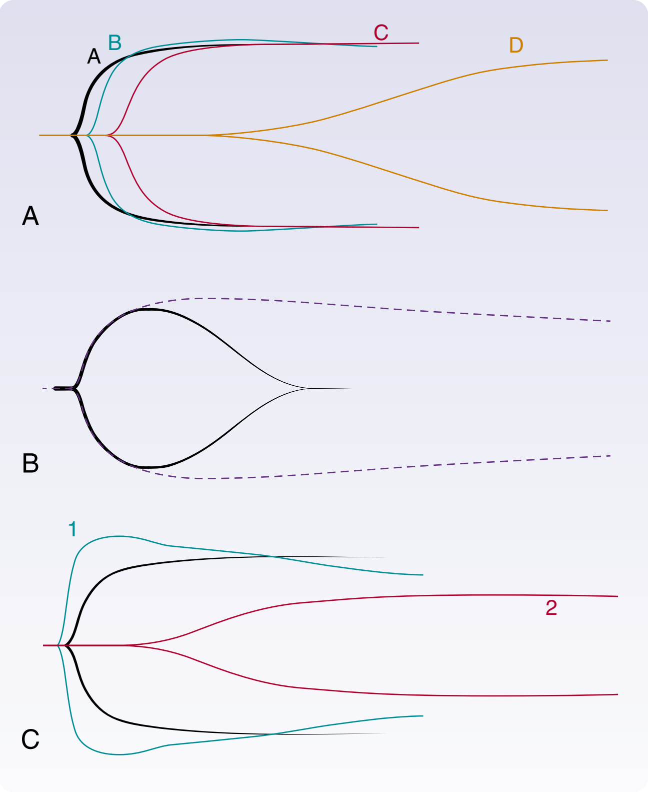

FIGURE 100.4 (A–C) Thromboelastography (TEG) tracings for disorders of hemostasis. (A) Hemophilia. The R-value will be prolonged when the coagulation factor level becomes significantly low. In mild cases, the parameters may be normal *(curve A),* but the R time will get progressively longer with decreasing levels of the factor (as seen from *curve B to C to D*). In more severe cases, the thrombin may be low enough to affect the clot strength. (B) Primary fibrinolysis. The LY30 will be elevated significantly, and the maximum amplitude (MA) will be lower than normal. This is because the clot is breaking down faster than it can finish forming. The *black* curve peaks earlier and with a lower MA than the baseline *dashed purple curve;* however, the R and K times in the two curves are overlapping and roughly equal. (C) In stage 1 disseminated intervascular coagulation (DIC) *(blue curve),* the patient will be hypercoagulable (both enzymatic and platelet), with moderately elevated LY30, elevated MA, and elevated alpha angle. The R time and K time are also decreased. The lysis is a physiologically appropriate response to an underlying thrombotic condition. If this hypercoagulable state is not treated effectively, the patient transitions into stage 2 DIC *(red curve),* which involves consumptive coagulopathy. In stage 2 DIC, all parameters become hypocoagulable, reflected by prolonged R and K times and decreased MA and alpha angles. *K time,* Kinetical time; *LY30,* percentage of lysis 30 minutes after maximal clot strength; *R time,* reaction time. (Courtesy Anahita Dua, MD, MBA, MSC and Haemonetics Corporation.)

The reaction time, or R time, measures the time to develop clot formation. The R time is an assessment of coagulation factor activity in secondary hemostasis and the formation of thrombin. The kinetical time, or K time, measures the time until the clot has reached a specific viscosity. The K time reflects fibrin cross-linking and fibrin levels. Similarly, the alpha angle is a measurement of the slope or rate of the fibrin polymerization during the K time. The maximum amplitude (MA) is the highest amplitude of the TEG curve and represents the peak viscosity or strength of the clot.[51] The last variable measured with TEG is the LY30, which evaluates the percentage of clot breakdown or fibrinolysis over 30 minutes.

Abnormalities of the values recorded with TEG are helpful in guiding management of the bleeding patient. For example, a prolonged R time may prompt transfusion of FFP to supplement deficient or dysfunctional coagulation factors.[50] A prolonged K time or a decreased alpha angle may prompt cryoprecipitate transfusion to correct low fibrin levels and improve clot strengthening. Decreased MA suggests low platelet function, so platelet transfusion or DDAVP may be initiated. An elevated LY30 value may trigger TXA administration to decrease fibrinolysis. However, the accuracy of TEG may be worse for patients taking anticoagulants or antiplatelet therapy, which should be taken into consideration for each individual patient.

Several variations of TEG exist and can be used to test specific components of hemostasis. ROTEM is similar to TEG because ROTEM measures the viscosity of whole blood to create a profile of hemostasis. However, ROTEM is different in that the cup with the blood sample remains fixed, and the pin within the cup oscillates. The tracing from a ROTEM provides similar information on clot formation, strengthening, and lysis, but the measurements are not interchangeable with those of a TEG. Different reagents can be added to the ROTEM sample to focus on specific parts of the coagulation cascade (e.g., intrinsic or extrinsic pathways).[50] TEG is used more often than ROTEM in trauma centers in North America because of its availability.

Management

Common Hemostatic Medications

Plasma. Human plasma is commonly used to replace coagulation factors in several coagulopathies. Plasma is separated from erythrocytes, platelets, and leukocytes in whole blood and then stored in various ways. Plasma contains all coagulation factors as well as fibrinogen, albumin, proteins C and S, antithrombin, and TFPI. Plasma from a single donor can be stored individually or combined into "pooled plasma."[52] FFP is the most common way to store plasma, and FFP must be thawed before transfusion. Plasma is frequently given empirically for reversal of vitamin K antagonists when PCC is not available, in emergency surgery, or for patients with consumptive coagulopathies.[49] Abnormal lab values such as prolonged INR or prolonged R time on a TEG often trigger plasma transfusion. However, individual response to FFP may vary based on severity of illness and sex, making it difficult to determine how aggressive providers should be with transfusion.[53]

Additionally, plasma transfusions are not without risk. Higher levels of plasma transfusion are associated with increased risk of infection, sepsis, multiple organ failure, transfusion-related acute lung injury, and acute respiratory distress syndrome.[54] Additionally, there have not been many trials demonstrating benefit of plasma in hemostasis because plasma is commonly given in conjunction with other blood products.[55] Therefore, plasma is often used in the setting of coagulopathy and as part of massive transfusion protocols; however, providers should be cautious and intentional with its use.

Prothrombin complex. PCC contains plasma-derived coagulation factors II, VII, IX, and X, along with proteins C and S. Because these concentrates consist of vitamin K–dependent factors, they are the first-line treatment for emergent reversal of vitamin K antagonists. Compared with plasma, PCC has a lower rate of transfusion reactions and are more readily available. Additionally, the high concentration of factors in PCC requires less volume to deliver the factors, reducing the risk of volume overload.[56] Thus far, there remains a need for randomized controlled studies to assess the use of PCC in the perioperative or acute blood loss settings.[49] Various studies have investigated the use of PCC in the setting of major trauma, in end-stage liver disease, and as a reversal agent for anti-Xa inhibitors and suggest benefit from PCC in correcting deficiencies of vitamin K–dependent factors and improving survival after major trauma; however, further investigation is needed to assess the risk of venous thromboembolic events with PCC and the individual benefit of PCC as part of a transfusion protocol.[56]

Cryoprecipitate. Cryoprecipitate contains FVIII and FXIII, fibrinogen, fibrinonectin, anti-thrombin, and vWF. Fibrinogen is the first coagulation factor to be depleted during acute bleeding.[55] Hypofibrinogenemia after trauma is associated with the highest risk of massive transfusion requirements and mortality.[57] Therefore, cryoprecipitate is often considered for management of hypofibrinogenemia. Compared with FFP, cryoprecipitate is transfused in lower fluid volumes and contains higher concentrations of fibrinogen.[46] The Prospective Observational Multicenter Major Trauma Transfusion (PROMMTT) study was a multicenter observational study of transfusions given to adult trauma patients. As part of a secondary analysis, the use of cryoprecipitate and in-hospital mortality at 6 hours, 24 hours, and 30 days were also investigated. Patients who received cryoprecipitate were more injured and had higher physiologic abnormalities than those who did not receive cryoprecipitate; however, no significant survival benefit with cryoprecipitate transfusion was found.[58] However, the incorporation of cryoprecipitate in institutions' massive transfusion protocols varied greatly in the PROMMTT study, making conclusions regarding the true effect of early or structured cryoprecipitate transfusion protocols difficult. Thus, further studies are warranted to guide indications, timing, and quantity of cryoprecipitate transfusion.

As with many blood transfusion products, adverse reactions secondary to cryoprecipitate infusions include acute hemolytic transfusion reaction, anaphylactic response, transfusion-associated circulatory overload, febrile nonhemolytic transfusion reaction, and transfusion-related acute lung injury.[46] Patients receiving transfusions should be monitored closely, and the infusion should be stopped immediately if there is concern for any adverse reaction.

Desmopressin. Desmopressin, also known as *1-deamino-8-D-arginine vasopressin* or *DDAVP,* is a synthetic compound that mimics some of the functions of autogenous vasopressin. DDAVP stimulates V2 receptors, leading to release of endothelial vWF and increased FVIII.[59] DDAVP can be delivered to the patient intravenously, intranasally, or subcutaneously. Because DDAVP is a vasopressin analog, it also has antidiuretic hormone effects, which can lead to severe hyponatremia or seizures. Additional potential side effects of DDAVP include flushing or cardiovascular complications.[60] However, evidence indicates that DDAVP is useful in hemostasis for patients with hemophilia, vWD, and even chronic liver or renal disease.[59] However, this response is transient and needs to be timed with the planned surgery in order to have the desired effects on hemostasis in the perioperative period.[13] Repeat doses of DDAVP can be administered to maintain desired vWF and FVIII activity levels. Close monitoring of fluid status and sodium levels should be maintained while patients are receiving DDAVP.

Tranexamic acid. TXA is administered to reduce bleeding by inhibiting fibrinolysis. TXA binds to plasminogen to inhibit the conversion of plasminogen into plasmin, therefore preventing the degradation of fibrin. TXA also plays an antiinflammatory role by inhibiting complement production.[61,62] For these reasons, TXA may be given in the setting of hyperfibrinolysis, such as when the LY30 is elevated on a TEG or fibrin degradation products are increased.

TXA has been used in multiple settings, including obstetrical bleeding, traumatic hemorrhage, and major surgeries. The Clinical Randomization of an Antifibrinolytic in Significant Hemorrhage (CRASH) Trials investigated 28-day mortality of trauma patients who received TXA within 3 hours of injury and those who did not receive TXA.[63] The CRASH trials support the use of TXA within the first 3 hours after injury; however, the dosage and interval of administration remain unclear.[64] The Pre-hospital Antifibrinolytics for Traumatic Coagulopathy and Hemorrhage (PATCH-Trauma) trial was a randomized, placebo-controlled trial investigating the effects of TXA given before hospital admission on survival and functional outcomes.[63] There was no significant difference in 6-month survival, with favorable functional outcomes between patients who received TXA and those who did not. However, TXA risks include thromboembolic events and seizures.[62] Therefore, further studies will be important to understand the impact of TXA and the risks of thromboembolic events associated with TXA administration.

Special Considerations

Von Willebrand disease. For patients with vWD, the specific type of vWD drives the choice of therapy. Patients with type I vWD respond well to DDAVP because it triggers the release of endothelial vWF that has already been synthesized. On the other hand, patients with type III vWD have complete absence of vWF synthesis and therefore will not be able to release any vWF even with stimulation from DDAVP. Instead, direct replacement of vWF and FVIII can be administered for treatment of type III vWD and most type II vWD patients.[13] Particularly in vWD patients with active bleeding or who are undergoing surgery, it is recommended that their vWF and FVIII activity levels are normalized and maintained within normal range within the first 5 to 10 days postprocedure, depending on the type of procedure.[60]

Hemophilias. The mainstay of therapy for hemophilia is replacement of the deficient coagulation factors. Traditionally, products such as cryoprecipitate, PCC, and plasma were administered to replete coagulation factors. However, more targeted therapies, such plasma-derived or recombinant FVIII and FIX concentrates, have been developed for these patients.[16] Prophylactic regimens have been developed to prevent bleeding episodes and involve intravenous infusions of replacement factor concentrates several times weekly. Replacement factors with longer half-lives have been developed to reduce the frequency of prophylactic infusions.[65] DDAVP can also be considered for patients with mild

HA to help boost endogenous FVIII; however, DDAVP is not adequate for acute bleeding episodes. Novel gene transfer therapies involving viral vectors have also been studied to increase circulating coagulation factor levels; however, sustained increases in plasma factor levels have not yet been demonstrated.[15]

Emicizumab is a bispecific monoclonal antibody that simulates FVIII by binding activated FIX with FX.[66] Most importantly, because this compound is distinct from FVIII, it is not affected by FVIII inhibitors. The HAVEN 1 trial was a randomized study of patients with HA and inhibitors who were treated with or without emicizumab and showed that once-weekly subcutaneous delivery of emicizumab had 87% lower treated bleeding rates compared with patients who did not receive emicizumab. Thus, emicizumab may be used in prophylactic treatment regimens for congenital HA patients with and without inhibitors.[19]

Trauma-induced coagulopathy. In the setting of TIC, it is recommended to transfuse in a 1:1:1 ratio (plasma:platelets:red blood cells) in the early resuscitation phase to minimize the dilutional effect of crystalloid fluids and to replete coagulation factors. The Pragmatic, Randomized Optimal Platelet and Plasma Ratios (PROPPR) trial was designed to compare the safety and effectiveness of a 1:1:1 transfusion ratio with a 1:1:2 ratio.[58] This trial showed no difference in mortality at 24-hour or 30-day time points between the two groups; however, more hemostasis was achieved in the 1:1:1 group, with fewer deaths secondary to exsanguination. Other studies suggest that the TEG may have a beneficial role in guiding transfusion management compared with standard laboratory tests.

Surgical Management

Electrocautery and suture ligation are first-line therapies for active bleeding within a surgical field. The electrocautery sends a current through the tissue to induce hemostasis by sealing vessels using heat. Methods such as suture ligation or clip placement provide physical barriers to small branches of arteries and veins to stop bleeding. Topical agents and biologically active agents may be used to control bleeding from microvasculature or diffuse ooze from impaired coagulation systems (Fig. 100.5).

Topical agents. Strategies for hemostasis intraoperatively include topical agents with several different underlying functions. Some agents, such as bone wax, act as a physical barrier to assist with tamponade in the surgical field and prevent further bleeding.[67] Overall, these rely on relatively normal-functioning coagulation factors and platelets. Bone wax is a nonabsorbable compound and has potential to become a source of infection as a foreign body. Ostene is a novel hemostatic compound that is used as an alternative to bone wax because it is absorbable and does not affect bone healing or cause an inflammatory response.[68]

Gelatin-based compounds (e.g., Gelfoam or Surgifoam) made from porcine skin are activated on contact with blood and then act as a matrix to promote platelet aggregation and clot formation. Similarly, collagen-based compounds (e.g., Avitene) increase platelet function and activate the intrinsic coagulation pathway for hemostasis.[69] Therefore, microfibrillar collagen agents are more successful in hemostasis for heparinized patients; however, these agents may be less effective for patients with thrombocytopenia. These agents exist in various preparation forms, such as powder, dry sheets, or paste, and may be left in situ to break down over the course of 4 to 6 weeks.

Cellulose-based agents (e.g., Surgicel) are made from oxidized cellulose and lead to hemostasis via multiple factors. First, activation of the agent promotes platelet aggregation and adherence. Second, the low pH of the product has a caustic effect that results in coagulative necrosis and hemostasis. Third, the product expands when hydrated, leading to hemostasis by tamponade. Cellulose-based agents also have antimicrobial properties and can be left in the surgical field until breakdown in several weeks.

Caustic agents, such as silver nitrate or zinc chloride, induce hemostasis by causing "protein precipitation and vessel occlusion."[68] These are primarily used on superficial wounds and should be avoided in larger, open wounds. Additional benefits of these compounds include antimicrobial properties and the ease of application in a clinic setting.

Microporous polysaccharide hemospheres (MPH) are a newer option for topical hemostasis. MPH are hydrophilic and easily bind to platelets and factors needed to form a fibrin clot. The structure of the MPH also acts as a matrix for clot development once they contact blood.[67]

Synthetic sealants, such as cyanoacrylate or polyethylene glycol polymers, can also be used as physical barriers in the setting of bleeding. These compounds contain monomers that rapidly polymerize upon contact, creating an adhesive to seal a wound. BioGlue is made of glutaraldehyde and bovine albumin and is another alternative for topical hemostasis. It quickly transforms into an adherent scaffold that seals tissue or synthetic grafts, making it an option for sealing larger vessels or anastomoses.[67]

Biologically active agents. Thrombin can be prepared from bovine, human, or recombinant sources. Thrombin is applied directly to the surgical field and triggers the conversion of fibrinogen to fibrin, creating a clot. Thrombin also upregulates its own production via activation of factors V, VIII, and XI.[68] Thrombin is often used in conjunction with gelatin-based topical agents to further promote local hemostasis.[67] As previously discussed, rare cases of bovine thrombin–induced coagulopathy have been documented after exposure to bovine thrombin preparations.

Fibrin sealants (e.g., Tisseal, Artiss) contain fibrinogen, thrombin, calcium, and FXIII to enhance the common pathway of the coagulation cascade.[69] Some mixtures also include an antifibrinolytic, such as TXA or aprotinin, to further stabilize a nascent fibrin clot.[67] These sealants are biodegradable and are generally reabsorbed in the first 2 weeks after application. Fibrin sealants are kept frozen and then thawed into a liquid or spray at the time of use. Of note, this type of agent is not recommended in higher-volume arterial or venous bleeding because the developing thrombus could be dislodged by blood flow, resulting in an embolic event.[68]

"Flowable agents" describes a class of hemostatic products that combine active with passive hemostatic agents, combining a gelatin-based agent to serve as a scaffold for clot formation with an active biologic agent, such as topical thrombin, to activate the coagulation cascade.[67] This multifactorial mechanism is used in products like Floseal and Surgiflo.

Spontaneous intramuscular hematomas. Spontaneous intramuscular hematomas are relatively rare events. Most are managed conservatively; however, some can have severe sequela requiring additional interventions.[70,71] The pathophysiology of spontaneous intramuscular hematomas is not fully elucidated, although associated risk factors include advanced age, anticoagulation or antiplatelet therapy, hematologic disorders, and chronic kidney disease.[70–72] Clinical presentation is dependent on anatomic location of the hematoma. Rectus sheath hematomas are associated with damage to the superior or inferior epigastric arteries or their branches, which can result in abdominal pain, distention, ecchymosis, or peritonitis.[70,73] Retroperitoneal or iliopsoas muscle hematomas may be difficult to diagnose initially because of their

location. When large, iliopsoas hematomas can cause groin pain, muscle dysfunction, or compression of the femoral nerve, resulting in paresthesia or paralysis.[71]

Because of the deeper location of intramuscular hematomas, computed tomography (CT) imaging is the gold standard to evaluate size and location of hematomas.[70,73] Specifically, CT angiography is advantageous in identifying any vessels actively bleeding into the hematoma.[73] Initial management involves fluid resuscitation, pain control, reversal of anticoagulation, and blood transfusion if necessary. If the patient develops hemodynamic instability, ongoing transfusion requirements, neurologic symptoms, persistent pain, or compartment syndrome, further intervention may be warranted. Percutaneous arterial embolization is commonly the first-line therapy to stop further bleeding into the hematoma.[70,72,73] More invasive surgical decompression with ligation of bleeding vessels can be considered for severe cases without obvious target vessels for embolization.

Postoperative hematomas. Postoperative hematomas are a common complication in all surgical subspecialties. Contributing factors include inadequate hemostasis, sustained capillary bed bleeding from raw surfaces, surgical dead space, and coagulopathy.[74] Hypertension (described as a mean postoperative systolic blood pressure of 160 mm Hg) has also been found to be associated with hematoma formation after panniculectomy.[75] In patients with hematomas, risks and benefits should be weighed regarding cessation of anticoagulation or antiplatelet therapy. Commonly, these agents are discontinued until stabilization or resolution of the hematoma.

The management of postoperative hematomas is determined by the hematoma's anatomic location, size, and effect on surrounding tissues. Small postoperative hematomas generally self-resolve and do not require surgery. Larger hematomas can cause pain, wound dehiscence, and ischemic necrosis of overlying skin. These larger hematomas also pose a risk of infections that could result in additional complications. Special care should be taken for neck hematomas. Expanding hematomas in the neck region can compromise the airway and therefore require immediate surgical decompression.[76] For hematomas that pose a risk of skin necrosis and/or infection, evacuation should be performed. Evacuation of a hematoma involves reopening the wound, followed by mechanical expression, suctioning, or curettage.[77] The wound can then be reclosed or left open with packing or negative-pressure vacuum therapy. Temporary drains may be placed in the surgical bed to prevent reaccumulation of fluid and eliminate dead space; however, the drains have potential to become sources of infection and prolong hospitalization.[78] Further studies are warranted to determine the risks and indications for prophylactic surgical drain placement.

THE HYPERCOAGULABLE STATE

Pathophysiology of Venous Thromboembolism and Arterial Thrombosis

Venous thromboembolism (VTE), which includes DVT and PE, is a common source of morbidity and mortality in trauma patients and in patients undergoing major surgery. Overall, it is estimated to cause >50,000 deaths per annum in the United States, with ~25% of VTEs occurring in the perioperative period.[79] Although risk of VTE varies depending on patient risk factors and surgical procedure, the underlying pathogenesis of VTE is best described by Virchow's triad.

Virchow's triad depicts venous thrombosis as the result of an interplay among procoagulant activity in the blood (hypercoagulable state), vein wall damage (endothelial damage and dysfunction), and venous stasis.[80] Hypercoagulability of the blood can be a result of hereditary or acquired disorders, which are described in the next section of the chapter. Particularly in surgery or trauma, VTE can be induced by vein wall damage (endothelial damage and dysfunction), which exposures blood to extravascular TF. Although damage to the endothelium is one of the culprits of VTE, VTE can also occur in trauma or major surgery without endothelium disruption. In this circumstance, hypoxia or inflammatory cytokines stimulate endothelial cells and circulating monocytes to express TF and induce endothelial cell expression of the adhesion molecule P-selectin. P-selectin then tethers circulating monocytes expressing TF, initiating a procoagulant milieu.[80] In VTE, subsequent thrombin generation from TF:FVIIa activates platelets, which release polyphosphate, while activated neutrophils trapped within venous thrombi extrude neutrophil extracellular traps (NET). Together, polyphosphate and NETs initiate the intrinsic pathway by activating FXI, propagating a procoagulant environment. Lastly, the third branch of Virchow's triad, venous stasis, plays a role in VTE by creating a hypoxic environment. A hypoxic environment has been demonstrated to increase procoagulants, as previously mentioned, and downregulate antithrombotic proteins expressed by endothelial cells, such as thrombomodulin and endothelial protein C receptor.[80] Inhibiting particular steps in these processes can reduce the risk of VTE.

Arterial thrombosis can also occur in our perioperative surgical patients but is much less common. Risk of arterial thrombosis is largely dependent on type of surgery and coexisting risk factors, such as cardiovascular disease, inherited thrombophilia, and other acquired hypercoagulable disorders. In our surgical patients, arterial thrombosis can present as acute stroke, myocardial infarction (MI), or acute limb/mesenteric ischemia. The pathophysiology is similar to Virchow's triad and can be related to the activation of platelets, dysregulated blood flow enforcing shear stress, endothelial damage and dysfunction, and/or a hypercoagulable state. The following section describes inherited (Table 100.4) and acquired risk factors that predispose patients to VTE and/or arterial thrombosis.

Inherited Risk of Thrombosis

Factor V Leiden mutation. Factor V Leiden (FVL) mutation is the most prevalent inherited thrombophilia found in White populations.[81] In Europeans or those with European ancestry, the prevalence of a heterozygous or homozygous mutation is 4.7% and 0.06% to 0.25%, respectively.[82] The FVL mutation predisposes patients to VTE as a result of a gain-of-function mutation that causes a single-nucleotide change at amino acid 506. At this point in the sequence, arginine is changed to glutamine, which results in resistance to activated protein C, a major natural anticoagulant. Typically, activated protein C cleaves FV to inhibit its procoagulant activity; however, this action is slowed with the point mutation at amino acid 506. Other polymorphisms in the FV gene have been identified, but these variants do not appear to have as strong of an association with VTE.[83] FVL mutation's risk of thrombosis is dependent on its heritability. The relative risk of VTE is approximately sixfold to eightfold for heterozygotes, whereas it is eightyfold for homozygotes.[83] This risk is increased by other genetic or environmental risks, such as oral contraceptive (OCP) use, pregnancy, protein S deficiency, hyperhomocysteinemia, and/or increasing age. Particularly in pregnancy, FVL mutation has been associated with recurrent pregnancy loss. FVL mutation has also been associated with increased risk of recurrent VTE. In a meta-analysis including 31 prospective observational cohort studies and 24 publications summarizing 13,571 patients

TABLE 100.4 Inherited Thrombophilias

INHERITED THROMBOPHILIA	UNDERLYING PATHOPHYSIOLOGY	DIAGNOSTIC MODALITIES
Factor V Leiden mutation	Gain-of-function missense mutation of arginine to guanine at position 506 causing APC resistance	Functional assay of APC resistance using plasma or direct DNA-based tests[a]
Prothrombin gene mutation	Missense mutation of guanine to adenine at position 20210 causing increased thrombin synthesis	DNA-based methods[b]
Protein C deficiency	Monoallelic mutations in long arm of chromosome 2. Over 500 mutations have been identified.	Functional assays (clot-based or chromogenic). To minimize false positives, cease vitamin K–antagonism treatment.[c]
Protein S deficiency	*PROS1* gene mutation on chromosome 3 causing disrupted interaction with APC and TFPI	Immunoassay or functional clot-based methods. To minimize false positives, cease oral contraceptive or vitamin K–antagonism treatment.[d]
Antithrombin deficiency	*SERPINC1* gene mutation causing inability to clear thrombin and factor Xa	Functional chromogenic assay or immunoassay. DOAC can falsely increase antithrombin levels if using thrombin-based functional assay.[e]
Antiphospholipid antibody syndrome	Autoimmune systemic disorder causing persistent antiphospholipid antibodies, including LA, aCL, and aB2GPI.	Testing for presence of LA, aCL, and aB2GPI[f]

[a] DNA-based tests may not capture rare variants; therefore recommend using plasma.

[b] Functional assays not performed because there is variability in plasma prothrombin levels.

[c] Immunoassays not performed because not able to detect type II deficiencies.

[d] Diagnosis can be difficult because of variations in levels of protein S related to age (lower at birth), sex (females with 15% less protein S), and acquired conditions (pregnancy, oral contraceptive use). Need confirmation with second blood sample because of variations in protein S levels.

[e] Suspect with antithrombin activity <80%. Can use functional chromogenic assays measuring thrombin or FXa.

[f] Retest blood after 12-week interval to confirm diagnosis.

aB2GPI, Anti-*B2*Glycoprotein I antibodies; *aCL,* anticardiolpin; *APC,* activated protein C; *DOAC,* direct oral anticoagulation; *LA,* lupus anticoagulant; *TFPI,* tissue factor plasma inhibitor.

with provoked, unprovoked, or mixed VTE, FVL heterozygous mutations increased the risk of recurrent VTE by 42%.[81] Meanwhile, homozygous FVL mutation significantly increased risk of recurrence, with an odds ratio of 2.65.[83] Although not as common, FVL mutation is also associated with arterial thrombi presenting as ischemic stroke. In a 2019 meta-analysis using 68 eligible studies that described patients with arterial ischemic stroke with concomitant inherited thrombophilia, a total of 11,916 patients were identified to demonstrate that FVL was associated with a 1.25 odds ratio of acute ischemic stroke.[84]

Prothrombin gene mutation. Prothrombin G20210A gene mutation is the second most common inherited thrombophilia. Overall prevalence of heterozygous prothrombin gene mutation is estimated at 2%, whereas reports of homozygous mutations are clinically rare.[85] Prothrombin gene mutation develops from a missense mutation (guanine to adenine) at position 20210 of the prothrombin gene, which results in increased prothrombin synthesis.[86] The gain-of-function mutation leads to increased synthesis of thrombin and therefore increased risk of thromboembolic events. In patients with prothrombin gene mutation, the proposed increased risk of developing a first episode of VTE is threefold.[85] Typically, those who are carriers of the prothrombin gene mutation and have a thrombotic event will present most commonly with a DVT of the lower extremities or PE; however, thromboses in atypical sites, including portal, hepatic, or cerebral veins, have been reported. In these patients, prothrombin gene mutation carriers have a fourfold increased risk of developing portal vein thrombosis.[82] Interestingly, prothrombin gene mutation carriers do not have an increased risk of recurrent DVT in comparison to patients who do not carry this mutation but have a history of DVT.[82] Furthermore, polymorphisms of this gene defect do not have a clear association with VTE. In regard to arterial thrombi, prothrombin gene mutation has been associated with an increased risk of acute ischemic stroke in young patients, regardless of zygosity.[87] Depending on the study, the odds of an acute stroke in patients with PTM have ranged from 1.48 to 7.19.[87]

Protein C deficiency. Protein C is a vitamin K–dependent zymogen that is activated by the endothelial thrombomodulin-thrombin complex and protein C receptor. Its activation leads to its anticoagulant property, inhibiting FV and FVIII. The deficiency of protein C disturbs the hemostasis between procoagulant and anticoagulant proteins, thereby predisposing individuals to predominately VTE. Protein C deficiency results from pathologic mutations in the long arm of chromosome 2.[88] Monoallelic heterozygous deficiencies occur in 0.2% to 0.5% of the population and are inherited in an autosomal dominant manner.[88] Homozygous or compound heterozygous protein C deficiency is extremely rare. So far, >500 mutations in protein C have been identified.[89] Given the large quantity of mutations, protein C deficiencies have been further categorized into type 1 or type 2 deficiencies. Type 1 mutation is described as reduced concentration of protein C antigen and activity. Type 2, which is less common, results in dysfunctional protein C but normal protein levels.[90] The risk of VTE varies among patients with mutations in the protein C gene and is likely related to the degree of deficiency and whether other coexisting VTE risk factors exist. For example, the clinical presentation of protein C deficiency varies from asymptomatic patients to VTE to acute life-threatening complications such as purpura fulminans or DIC.[89] In regard to VTE alone, risk can be increased as high as tenfold to fifteenfold, with the first VTE usually occurring under the age of 50.[88,91] These patients are also at increased risk of recurrent VTE. Protein C deficiency has been associated with multilocation arterial thrombosis, with patients presenting with acute stroke, MI, and critical limb ischemia.

Protein S deficiency. The incidence of protein S deficiency is rare, occurring in 0.03% to 0.13% of patients, with prevalence higher in the Southeast Asian population.[92,93] Protein S interacts with TFPI and is a vitamin K–dependent cofactor for activated protein C that is synthesized in the liver, vascular endothelium, monocytes, and megakaryocytes.[92] Protein S exists in the plasma in two forms: Approximately 60% is bound to complement component C4b-binding protein, and 40% is free.[86] The free component of protein S is the active anticoagulant. Protein S deficiency is inherited in an autosomal dominant fashion with mutations in the *PROS1* gene on chromosome 3. More than 200 mutations have been reported in the *PROS1* gene, and their effect can manifest in one of three forms: reduced levels of total and free protein (type I), normal levels of protein but reduced activity (type II), or normal total protein but reduced active (free) protein (tyle III).[86] All three subtypes have a similar clinical phenotype.

Patients with protein S deficiency have a higher risk of VTE and arterial thromboembolism (ischemic stroke). This risk is compounded by other genetic and acquired thrombophilic deficiencies. Acquired deficiencies include OCP, surgery, infection, pregnancy, and liver disease.[93] Particularly during inflammation, pregnancy, or usage of OCP, C4b-binding protein will increase, thereby redistributing protein S into a quiescent state.[86] In patients with arterial thromboembolism from protein S deficiency, the levels of protein S are variable, suggesting different mutations could exist that elicit a stronger thrombotic effect.[92] Protein S deficiency has also been linked to excessive blood clotting and immune hyperactivation seen in COVID-19 disease.[94] This hypercoagulability has been hypothesized to be the result of the SARS-CoV-2 papain-like protease cleaving protein S and thereby disrupting its ability to interact with both activated protein C and TFPI. In summary, any disruption of protein S, from inherited or acquired states, can increase patient risk of VTE or arterial thrombosis.

Antithrombin deficiency. Antithrombin is an anticoagulant that irreversibly binds thrombin; FX; and to a lesser degree, FIXa, XIa, XIIa, tPA, urokinase, trypsin, plasmin, and kallikrein. Inherited antithrombin deficiency is a rare autosomal dominant disorder, affecting 0.02% to 0.2% of the population.[9] Antithrombin deficiency is predominately caused by genetic defects in *SERPINC1* and is considered the most severe form of thrombophilia.[95] To date, 364 variants have been identified. When diagnosing congenital antithrombin deficiency, two types can be distinguished. *Type I* deficiency describes a reduction in antithrombin production, whereas *type II* describes a defect in protein function.[91] These distinctions are relevant because homozygous type I deficiency is thought to be incompatible with life. Homozygous type II is thought to cause severe VTE, whereas heterozygous type II is less virulent.

Patients with antithrombin deficiency compatible with life enter a hypercoagulable state with risk of venous and arterial thrombosis as a result of the inability to clear thrombin and FXa from the circulation.[9] However, the risk of arterial thrombosis is weaker than that for VTE. Risk of VTE has been reported to be as high as a fiftyfold increase.[95] VTE in these patients typically occurs as DVT of the legs, arms, and pulmonary arteries. VTE can also occur in unusual sites, including cerebral or sinus, mesenteric, portal, hepatic, renal, and retinal veins. Given exogenous heparin functions to promote antithrombin activity, patients with antithrombin deficiency have varying degrees of heparin resistance. Although antithrombin deficiency is certainly an inherited thrombophilic disorder, an acquired disorder is also seen with certain disease processes, including (1) transient or permanent reductions in hepatic synthesis and (2) consumption of plasma antithrombin at a faster rate than it can be produced. Some disease processes that reduce antithrombin include liver disease, DIC, active thrombosis, and proteinuria.

Antiphospholipid antibody syndrome. Antiphospholipid (aPL) syndrome is an autoimmune systemic disorder characterized by arterial, venous, or small vessel thrombosis and pregnancy complications in the setting of documented persistent antiphospholipid antibodies, including lupus anticoagulant (LA), moderate-high titer anticardiolipin (aCL), or *anti-B*2Glycoprotein I antibodies (aB2GPI).[96] The estimated prevalence is 0.05%, which is based on a cohort from Olmsted County, Minnesota.[97] The pathogenesis of aPL-mediated coagulation and fibrinolysis disruption is recognized to be related to aPL antibodies engaging with cell surface phospholipids and phospholipid-binding proteins, which activate platelets, monocytes, and endothelial cells. aPL antibodies are also recognized to upregulate TF and activate adhesion molecules, proinflammatory cytokines, neutrophils, and complement.[97]

The clinical manifestations are broad and include VTE in the lower extremities; arterial thrombosis in the cerebral arteries; and microvascular thrombi in the skin, eyes, heart, lungs, kidneys, and other organs. Obstetric complications include recurrent early miscarriages (<10 weeks), preterm delivery for preeclampsia with severe features of placental insufficiency, and fetal growth restrictions.[98] aPL syndrome can also manifest as catastrophic aPL syndrome, which is rapid-onset thrombosis in multiple vascular beds leading to multiorgan failure. Catastrophic aPL syndrome usually occurs in a small subgroup of patients and can be precipitated by a triggering event, such as infection, neoplasm, or surgery. Other manifestations of aPL syndrome can present as livedo reticularis, thrombocytopenia, cardiac valve damage, or nephropathy.

Risk of venous, arterial, or obstetric complications depends on antibody characteristics and other clinical factors.[96] Recent recommendations define high risk as the persistent presence of LA, double-aPL syndrome (any combination of LA, aCL, and aB2GPI), or triple-aPL syndrome (LA, aCL, aB2GPI) or the presence of persistently high titers.[99] Risk is further compounded by transient or acquired factors, such as smoking, prolonged immobilization, surgery, OCP, and so forth. In the prospective multicenter observational study Predictors of Pregnancy Outcomes: Biomarkers in Antiphospholipid Antibody Syndrome and Systemic Lupus Erythematosus (PROMISSE), the researchers identified LA as the strongest independent predictor of adverse pregnancy outcomes beyond 12 weeks' gestation.[96] Because of the relevance of each of these antibodies, testing includes identifying the presence of LA, aCL, and B2GPI with repeated testing at least once after an interval of 12 weeks. Repeated testing is recommended to monitor for transient elevations that can occur from infection, inflammation, or pregnancy.

Hyperhomocysteinemia. Hyperhomocysteinemia can be an inherited or acquired disorder that leads to cardiovascular, cerebrovascular, and thromboembolic disease. The most common genetic mutation resulting in elevated levels of homocysteine occurs in the enzyme methylenetetrahydrofolate reductase (MTHFR). The missense mutation results in MTHFR deficiency, dysregulating folate metabolism and homocysteine synthesis.[100] Another genetic mutation resulting in elevated levels of homocysteine involves defects in the transsulfuration pathway (cystathionine b-synthase deficiency). Acquired hyperhomocysteinemia can occur from deficiencies of folic acid, vitamin B_6, vitamin B_{12}, or chronic diseases (e.g., high blood pressure, diabetes mellitus, obesity, kidney failure, medications such as atorvastatin, and hypothyroidism). Approximately 5% to 7% of the general population is expected to have at least mild elevations in homocysteinemia, defined as a homocysteine level greater than 15 μmol/L.[101]

It is proposed that hyperhomocysteinemia leads to arterial and venous thrombosis by damaging endothelial cells, promoting inflammation, and increasing oxidative stress. At this time, data are controversial regarding whether hyperhomocysteinemia results in recurrent VTE.[102] In regard to treatment, reduction of homocysteine levels and its effect on cardiovascular and thromboembolic diseases is dependent on the type of disease. For example, studies have only demonstrated homocysteine-lowering therapies (folic acid, vitamin B_{12}, and vitamin B_6) to have a benefit in patients with homocystinuria; otherwise, homocysteine-lowering therapies remain controversial.[103]

Acquired Risk of Thrombosis

Cardiovascular disease. In this section, the pathophysiology of arterial thrombi in patients with atherosclerosis and atrial fibrillation is discussed. In patients with atherosclerosis, activated platelets play a significant role in the pathophysiology of arterial thrombosis. In this setting, acute thrombosis is initiated from plaque rupture or erosion, resulting in exposure of collagen and chronic inflammatory cells. Although the pathology of plaque rupture and erosion differ and are outside the scope of this chapter, in both circumstances, high shear conditions induced from blood flowing through luminal irregularities at the site of plaque disruption result in the aggregation and activation of platelets.[104] The coagulation cascade is then initiated by the milieu of activated platelets and TF deposited within and expressed by macrophages and VSMC in the atherosclerotic lesion. Together, these processes create a unique thrombus rich in platelets and fibrin.

In patients with valvular heart disease, cardiomyopathies, or arrhythmias such as atrial fibrillation, the pathophysiology of arterial thrombosis also involves the key elements of blood stasis, endothelial dysfunction, and a hypercoagulable state. Studies have demonstrated that about 14% to 20% of patients who underwent transesophageal echocardiogram, cardiac surgery, or autopsy had left atrial thrombi.[105] Particularly in atrial fibrillation, insufficient atrial systolic function leads to blood stasis in the long and narrow left atrial appendage, which provides a site for intraatrial thrombus formation.[105] The stagnant blood flow also causes atrial endothelial microinjury/dysfunction, leading to the recruitment of immune cells.[106] These immune cells then secrete systemic inflammatory mediators, including C-reactive protein and interleukin (IL)-6, that invigorate a hypercoagulable state by initiating TF production in monocytes.[105] Patients with atrial fibrillation are also known to have elevated levels of vWF, fibrinogen, and P-selectin, factors associated with a hypercoagulable state.[105]

Infection. Infections, such as sepsis and COVID-19, induce a thromboinflammatory state that contributes to organ damage and thrombotic complications. Particularly in patients with COVID-19, observational studies demonstrated that the robust thromboinflammatory milieu induced macrovascular thrombosis in 10% to 30% of patients, which included those receiving standard-dose anticoagulation.[107] *Thromboinflammation,* in general, describes the complex interactions between inflammation and hemostasis, involving proinflammatory cytokines, chemokines, adhesion molecules, TF expression, and platelet and endothelial activation. The cells particularly relevant in thromboinflammation are platelets and neutrophils.

At the site of inflammation, platelets are the first cellular component adhering to the inflamed endothelium. Adherent platelets promote inflammation and organ damage by recruiting leukocytes, increasing vascular permeability, and promoting edema.[108] Of these functions, platelet-leukocyte interactions dictate the outcome of the thromboinflammatory state. The initiating step in thromboinflammation includes platelet recruitment of leukocytes and regulation of leukocyte function through multiple mechanisms, including direct and indirect receptor-ligand pairs; platelet secretion of inflammatory cytokines, chemokines, and growth factors (PF4, IL-1, RANTES, B-thromboglobulin, platelet-derived growth factor [PDGF], platelet-activating factor, CXCL7, migration inhibiting factor [MIF], TXA_2, serotonin); and platelet activation of the complement system.[108] Some of the receptor-ligand pairs include P-selectin glycoprotein ligand-1 (PSGL-1), GP1bα-macrophage 1 antigen (MAC-1), GPIIbIIIa-MAC-1 through fibrinogen, and CD40-CD40L. Furthermore, platelet activation of complement promotes endothelial cell activation, upregulation of TF, and further release of inflammatory cytokines.

Once leukocyte recruitment is initiated, neutrophils are the first at the scene. Neutrophils adhere to the endothelium and transmigrate through cell-cell interactions, where they then operate to phagocytose pathogens, degranulate, and release NET (NETosis). NET are netlike complexes consisting of chromatin DNA, histones, and neutrophil granule proteins, which are released into the extracellular space.[109] They function to bind pathogens and prevent their spread as well as ensure their elimination though antimicrobial and toxic factors. Although NET trap and kill pathogens, they can become pathogenic. In the recent literature, NET and activated platelets are observed in patients with sepsis and COVID-19, with high levels of NET-derived damage-associated molecular patterns (DAMP) correlating with thrombotic complications.[110] Thus, NET from recruited neutrophils are an important influencer of thromboinflammation. One example of NET influence on thromboinflammation is the effect of histones. Histones are one of the DAMP that propagate thromboinflammation as a result of activation of platelets, endothelial cells, and coagulation while impairing fibrinolysis.[110] Another NET-derived protein discussed in thromboinflammation is calprotectin (S100A8/A9). Calprotectin has been shown to have a prothrombotic effect by interacting with endothelial cells, activating platelets, and promoting fibrin generation as well as supporting immune cell recruitment and migration.

In summary, the reciprocal interactions between platelets and neutrophils propagate the inflammatory and thrombotic complications seen in thromboinflammatory disease states, such as sepsis and COVID-19. Not discussed in this section, other thromboinflammatory states that demonstrate this reciprocal interaction include DVT, sickle cell disease, stroke, and ischemia/reperfusion injury.

Neoplasia. Cancer is associated with an increased risk of VTE in multiple venous systems and arterial thrombosis. These disease processes are associated with worsened survival in cancer patients.[111] The incidence of cancer-associated VTE is increasing over time, with recent data estimating incidence to be 3.4%, whereas incidence of VTE in the general population remains around 0.36%.[112] This increase is likely a result of improved treatment options prolonging survival as well as increased surveillance imaging capturing incidental VTE. Although all cancer types predispose patients to VTE and arterial thrombosis, risk is largely influenced by type and stage of cancer, underlying comorbidities, and treatment-related factors (chemotherapy, protein kinase inhibitors, antiangiogenic therapy, and immunotherapy). Of all cancers, the highest thrombotic risk is observed in pancreas, stomach, and primary brain tumors. Other important risk factors include younger age, distant metastasis, prior history of VTE, and use of two-agent immunotherapy.[111–113] Recently, certain germline single-nucleotide polymorphisms (SNP) were also identified as risk factors for cancer-associated VTE. Cancer-driven mutations, such as *STK11, KRAS, CTNNB1, KEAP1, CDKN2B,* and *MET,* have also been implicated.[111] Although each cancer patient is unique in their risk of VTE and arterial thrombosis, mechanistically, cancer-associated thrombosis is likely driven by a combination of different pathways. These pathways include altering host biologic systems and tumor expression of procoagulant proteins that are released into the circulation.

Cancer has also been known to cause thrombocytosis, which is an independent risk factor for VTE. Although high platelet count increases risk of thrombosis, certain cancers increase levels of vWF and biomarkers associated with platelet activation (P-selectin, soluble CD40 ligand, thrombospondin-1, and platelet factor 4), which are associated with VTE.[111] Cancer is also associated with leukocytosis, which can be detected in 14% to 30% of cancer patients.[111] Leukocytosis is particularly relevant because activated monocytes express TF, whereas neutrophils in some cancers release NET that increase the prothrombotic milieu and proteases that degrade anticoagulant TFPI. Although many cancers affect host systems, tumor cells also express their own procoagulant proteins. Particularly, many cancer cells express high levels of TF and secrete extracellular vesicles with TF, creating a prothrombotic environment. Taken together, cancer-associated VTE and arterial thrombosis result from an interplay between the alteration of host defenses and tumor-specific expression of proteins that create a prothrombotic environment.

Pregnancy. Pregnant females are at four times greater risk of VTE than nonpregnant females of similar age from the time of conception through 6 weeks postpartum.[114] VTE is particularly concerning in this patient population because acute PE is one of the leading causes of maternal death in the Western world, with incidence of PE reported to be 1.72 cases per 1000 deliveries.[114,115] The hypercoagulable state induced by pregnancy is generally believed to be an evolutionary adaptation to reduce hemorrhage at the time of childbirth and prevent pregnancy loss. The risk of VTE in pregnant patients is compounded by prior history of VTE, hospitalization for an acute illness or cesarean-section delivery, and presence of an inherited thrombophilia. Mechanistically, pregnancy follows Virchow's triad. The hypoxic or inflammatory state created during early pregnancy triggers endothelial cell activation and adhesion receptors and leads to the activation of circulating leukocytes. Furthermore, increased estrogen levels elevate vWF through direct stimulation of endothelial cells and induce elevated plasma levels of clotting factors (FII, FVII, FVIII, FX, fibrinogen, and PAI-1) while reducing anticoagulants (protein S, protein C, and antithrombin).[116] Venous stasis in pregnancy occurs through the enhanced responsiveness of the vessel wall to hormonal changes and by the mechanical pressure of the gravid uterus. Thus, pregnancy induces a hypercoagulable state as a result of endothelial activation, alterations in procoagulant proteins, and venous stasis.

Smoking. Smoking is a known risk factor for the development of atherosclerosis and VTE. In regard to VTE, a retrospective analysis using 1.1 million participants from the Emerging Risk Factors Collaboration and the UK biobank found smoking to be associated with VTE, with a hazard ratio (HR) of 1.38.[117] The association was similar in magnitude for PE and DVT outcomes and similarly associated with provoked and unprovoked VTE. This study mitigated the previous thought that VTE risk was secondary to increased hospitalization for smoking-related diseases. Mechanistically, nicotine and other additives in cigarettes increase the percentage of reactive oxygen species; they reduce nitric oxide availability and generate an inflammatory and prothrombotic microenvironment.[82] The loss of nitric oxide–related protective effects (endothelial cell stability, vascular homeostasis, antiinflammatory and antioxidant properties) and increased reactive oxygen species work together to increase platelet activation. Thus, smoking is an independent risk factor for unprovoked VTE by increasing platelet activation and generating an inflammatory microenvironment.

Obesity. Obesity and other metabolic disorders are closely linked to chronic systemic inflammation and cardiovascular complications, including arterial and venous thrombosis. With regard to VTE, obesity is demonstrated to be an independent risk factor in males and females, with risk increased 6.2-fold. This risk is further increased when another acquired risk factor is present.[118] The relationship between obesity and arterial or venous thrombosis is dependent on adipose tissue's central role in both immunity and vascular homeostasis. Adipose tissue secretes bioactive peptides known as *adipokines*.[119] These molecules reach different organs and have a wide range of functions, including appetite control and pro- and antiinflammatory actions. Particularly in obesity, the adipokine leptin is elevated as a result of the body's resistance to leptin's function. Hyperleptinemia then upsets the endothelial leptin signaling, leading to a proinflammatory microenvironment and predisposing obese patients to VTE. Furthermore, increased visceral fat is associated with a prothrombotic state by increasing expression of PAI-1, an inhibitor of t-PA and u-PA. Increased visceral fat is also associated with decreased levels of the adipokine adiponectin, which is associated with increased inflammatory mediators, including monocyte chemoattract protein-1 (MCP-1). MCP-1 contributes to cardiovascular disease, such as atherosclerosis, by recruiting monocytes and macrophages into arterial vessel walls, thereby increasing obese patients' risk for arterial thrombosis. Additional mechanisms that increase the risk of VTE include hypoxemia induced by hypoperfusion of an expanding fat mass. In summary, obesity increases inflammatory mediators that create a prothrombotic environment, increasing the risk of both VTE and arterial thrombosis in the setting of endothelial damage or hyperactivation.

Warfarin-induced skin necrosis. Warfarin-induced skin necrosis is a rare but severe complication occurring in 0.01% to 0.1% of patients who receive the drug warfarin.[120] Warfarin is an anticoagulant that inactivates vitamin K–dependent clotting factors II, VII, IX, and X; protein C; and protein S. Patients at highest risk of this rare complication include those who have an underlying thrombophilia, those with an acquired prothrombotic risk factor, and those who have not been pretreated with an anticoagulant that is non–vitamin K dependent. Of the thrombophilias, protein C deficiency is the highest risk factor for warfarin-induced skin necrosis. Other thrombophilias observed in warfarin-induced skin necrosis include hyperhomocysteinemia, congenital deficiency of protein S, antithrombin III deficiency, and FVL mutation.

The pathogenic mechanism underlying warfarin-induced skin necrosis relies on the rapid fall of protein C compared with the other vitamin K–dependent clotting factors. The rapid fall of protein C induces a hypercoagulable state that promotes microthrombi in the cutaneous and subcutaneous venules.[121] Warfarin-induced skin necrosis is associated with higher loading doses and typically occurs in the first 10 days of initiation; however, case reports have described late-onset presentation, varying from months to years.[120] Clinically, skin lesions develop in areas of high amounts of subcutaneous fat and appear as poorly demarcated erythematous eruptions that are generally preceded by paresthesias. Next, edema develops in the dermis and subcutaneous tissues, with progression to hemorrhagic bullae within 24 hours. The hemorrhagic bullae signify irreversible injury and full-thickness coagulative skin necrosis. Diagnosis is generally from clinical suspicion. Laboratory workup may be performed to exclude other potential causes because protein C and S concentrations are not recommended for diagnostic workup given their poor sensitivity and specificity.[121]

Heparin-induced thrombosis. Heparin-induced thrombosis (HIT) occurs in 0.5% to 1% of patients exposed to unfractionated heparin and 0.1% to 0.5% of patients exposed to low-molecular-weight heparin (LMWH).[122] It is an immune disorder that results in IgG antibodies that complex to platelet factor 4/heparin and result in arterial and venous thrombosis, with a predilection for venous thrombosis.[123] The platelet factor 4–heparin–IgG (PF4-H-IgG) complex then binds to platelets, monocytes, and neutrophils. Platelet binding results in platelet activation, and monocytes begin to produce TF, thrombin, and inflammatory mediators.[123] Neutrophil activation leads to the release of NETs. The PF4-H-IgG typically binds the Fcγ receptor on these differing cell types to elicit a robust thrombotic response.

Clinically, HIT manifests as a drop in platelet count greater than 30% from baseline about 5 to 10 days after heparin administration. HIT more commonly occurs after orthopedic surgeries, cardiac surgery, and extracorporeal circulation. Presentation of thrombosis includes skin necrosis, venous limb gangrene, bilateral adrenal hemorrhage, and cerebral vein thrombosis.[122] Diagnosis can be achieved using platelet activation assays such as 14C-serotonin release assay, platelet aggregation assay, and flow cytometric assay (>95% high specificity but lower sensitivity, 56%–100%). High-sensitivity tests with lower specificity (30%–70%) include immunoassays.[123] Once HIT is confirmed, heparin should be stopped immediately.

Assessment of the Hypercoagulable State

The Inherited Hypercoagulable Disorders

Inherited thrombophilia should be suspected in patients with VTE at a young age (<50), disease in first-degree relatives (at least one parent or sibling), VTE in unusual locations, idiopathic or recurrent VTE, or history of recurrent miscarriage.[124] Historically, testing for inherited thrombophilia is controversial because testing can lead to overdiagnosis, defined as labeling an individual with the disease who would have otherwise been asymptomatic while causing physical, psychological, or financial harm if the condition is discovered.[125] In 2023, evidence-based guidelines from the American Society of Hematology intended to support decision-making about thrombophilia testing were developed. The guidelines discussed recommendations for testing thrombophilias most consistently associated with VTE, which include FVL mutation, prothrombin G20210A mutation, protein C or protein S deficiency, antithrombin deficiency, and antiphospholipid syndrome. Recommendations were labeled as "strong" or "conditional" according to the GRADE (grading of recommendations assessment, development and evaluation) approach. In summary, the panel issued a strong recommendation against testing the general population before starting OCP therapy. Conditional recommendations were made for the following scenarios: (1) patients with VTE associated with nonsurgical major transient or hormonal risk factors; (2) patients with cerebral or splanchnic venous thrombosis, in settings where anticoagulation would otherwise be discontinued; (3) individuals with a family history of antithrombin mutation or protein C or protein S deficiency when considering thromboprophylaxis for minor provoking risk factors and for guidance to avoid contraceptive therapy or hormonal therapy; (4) pregnant females with a family history of high-risk thrombophilia types; and (5) patients with cancer at low or intermediate risk of thrombosis and with a family history of VTE.[125] Further recommendations outlined by Middeldorp et al. can be found in Tables 100.5A and 100.5B.

Management of the Hypercoagulable State

Risk Assessment in Hospitalized Patients

Risk assessment models (RAM) have been developed to predict future risk of VTE in hospitalized patients and guide type, duration, and strength of prophylaxis.[126] One such model is the Caprini RAM. Since its introduction in 1991, Caprini RAM has been validated in over 250,000 patients in more than 100 clinical trials. It is a dynamic scoring tool that allows ongoing evaluation of surgical patients during their hospital course to determine risk of 30- and 60-day VTE. Risk factors included in this scoring system are age, medical history (including inherited/acquired thrombophilias), personal or family history of VTE, and surgery-related variables (type and length). The points allocated to each risk factor range from 1 to 5 and are determined by their association with VTE (Table 100.6).[127] Since its development, the Caprini RAM has proven to be consistent, thorough, and efficacious for risk stratification and selection of prophylaxis in postoperative surgical patients.

Medical Management—Role of Anticoagulation

The medical management of acute thromboembolism in patients with inherited or acquired thrombophilias is similar to that for the general population. Particularly for VTE, management consists of three phases: the initiation phase, treatment phase, and extended phase.[128] The initiation phase begins after the diagnosis of VTE and lasts 5 to 21 days. Treatment during this period is with parenteral or high-dose oral anticoagulation. The *treatment phase* describes the period after initiation and is considered complete after 3 months of standard therapeutic doses of anticoagulation. The *extended phase* describes the use of anticoagulants at full or reduced doses for the goal of secondary prevention. In the extended phase, there is no preplanned stop date. The decision to continue or stop anticoagulation is patient dependent. For patients with an inherited thrombophilia, the decision to continue or discontinue treatment should be guided by the 2023 ASH guidelines by Middeldorp et al. (see Tables 100.5A and 100.5B).[125] Anticoagulation for the hypercoagulable state includes parenteral anticoagulation (unfractionated heparin, LMWH, fondaparinux), direct oral anticoagulants (DOAC), parenteral anticoagulation followed by a DOAC, or parenteral anticoagulation overlapped by

TABLE 100.5A **Recommendations Derived From the 2023 American Society of Hematology Guidelines for Management of Venous Thromboembolism: Thrombophilia Testing (Part 1)**

QUESTION	RECOMMEND TESTING	TREATMENT
Should thrombophilia testing be performed in the following cases?		
Unprovoked symptomatic VTE	No	Short term
VTE provoked by surgery	No	Short term
Splanchnic VTE without cirrhosis, planning to continue anticoagulation indefinitely	No	Short term
Cerebral VTE planning to continue anticoagulation	No	Short term
Unspecified type of VTE	No	Short term
VTE by a nonsurgical major transient risk factor	Yes.	Indefinite
Females with VTE provoked by pregnancy	Yes	Indefinite
Females with VTE associated with COC	Yes	Indefinite
Cerebral VTE, planning to discontinue anticoagulation	Yes	Indefinite
Splanchnic VTE without cirrhosis, planning to discontinue anticoagulation	Yes	Indefinite
Should testing be performed to guide use of thromboprophylaxis for minor provoking risk factor?		**Treatment recommendation if tested and positive:**
Family hx of VTE and unknown thrombophilia status	No. Consider if multiple family members with VTE or if family member was young or patient preference.	
Family hx of VTE and thrombophilia	Yes[a]	Start thromboprophylaxis.
Family hx of thrombophilia but no VTE	Yes[a]	Start thromboprophylaxis.

Further remarks regarding recommendations can be found in the original guidelines. *Thrombophilia testing* refers to testing for antiphospholipid antibodies and all hereditary thrombophilia types. A positive family history is defined as having a first- or second-degree relative with VTE. These recommendations do not address homozygous defects or combinations of thrombophilia types, unless specified. Most recommendations are conditional based on GRADE approach.

[a] Designates if patient has family with history of antithrombin, protein C, or protein S deficiency.

COC, Combined oral contraceptive; *hx,* history; *VTE,* venous thromboembolism.

From Middeldorp S, Nieuwlaat R, Baumann Kreuziger L, et al. American Society of Hematology 2023 guidelines for management of venous thromboembolism: thrombophilia testing. *Blood Adv.* 2023;7(22):7101-7138.

TABLE 100.5B Recommendations Derived From the 2023 American Society of Hematology Guidelines for Management of Venous Thromboembolism: Thrombophilia Testing (Part 2)

QUESTION	RECOMMEND TESTING	TREATMENT
Should testing be performed in females with a family hx of VTE and/or family hx of thrombophilia?		
To guide use of COC[a]	No	
To guide HRT	No	
Selective testing to guide COC use	Yes[b]	Avoid COC.
Selective testing to guide HRT	Yes[b]	Avoid COC.
Selective testing to guide thromboprophylaxis during pregnancy	Yes, if known family hx of homozygous FVL, combination FVL and PGM, or antithrombin deficiency. Either testing if family hx of protein C or S deficiency.	Start antepartum thromboprophylaxis.
Selective testing to guide thromboprophylaxis postpartum	Yes, if first-degree family hx of VTE and homozygous FVL; combination FVL and PGM; antithrombin, protein C, or protein S deficiency. Yes, if second-degree family hx of VTE and combination FVL and PGM or antithrombin deficiency. Either testing if second-degree family hx of VTE and protein C or S deficiency.	Start antepartum thromboprophylaxis.
Should testing be performed in females with family hx of VTE but unknown thrombophilia?		
To guide OCP use	No	
To guide HRT	No	
Cancer-associated testing:		
In ambulatory cancer patients receiving systemic therapy with a family hx of VTE	Yes	Start antepartum thromboprophylaxis.

Further remarks regarding recommendations can be found in the original guidelines.[116] *Selective testing* refers to testing for a specific thrombophilia type. A positive family history is defined as having a first- or second-degree relative with VTE. These recommendations do not address homozygous defects or combinations of thrombophilia types, unless specified. *Either testing* refers to testing or not testing the patient. These recommendations are conditional based on GRADE approach.

[a] Indicates strong recommendation.

[b] Designates if patient has family with history of antithrombin, protein C, or protein S deficiency.

COC, Combined oral contraceptive; *FVL,* factor V Leiden mutation; *HRT,* hormonal replacement therapy; *Hx,* history; *PGM,* prothrombin gene mutation; *VTE,* venous thromboembolism.

From Middeldorp S, Nieuwlaat R, Baumann Kreuziger L, et al. American Society of Hematology 2023 guidelines for management of venous thromboembolism: thrombophilia testing. *Blood Adv.* 2023;7(22):7101-7138.

warfarin until INR is between 2.0 and 3.0 (see Table 100.3).[124] DOAC include oral direct factor Xa inhibitors (rivaroxaban, apixaban, edoxaban, and betrixaban) and direct thrombin inhibitors (dabigatran).[129] Currently, DOAC are the recommended treatment modality for VTE, including patients with homozygous FVL, combined prothrombin gene mutation and FVL, protein C or S deficiency, and antithrombin deficiency or mutation.[130]

Special considerations. In pregnant patients with or at risk of VTE, LMWH is preferred because it does not cross the placenta and is associated with a lower risk of HIT and osteoporosis.[114] In cancer-associated VTE, LMWH was considered the standard of care.[124,128] However, recent guidelines recommend an oral Xa inhibitor (apixaban, edoxaban, rivaroxaban) over LMWH in cancer-associated DVT. In patients with HIT, heparin should be stopped immediately, and direct parenteral thrombin inhibitors (bivalirudin, argatroban) or DOAC should be initiated (see Table 100.2).

Warfarin, a vitamin K antagonist, was previously the standard oral anticoagulant for patients with VTE. Patients on warfarin require bridging with parenteral anticoagulation 5 days earlier to mitigate the risk of warfarin-induced skin necrosis. Currently, warfarin is the recommended first-line oral therapy for patients who are unable to adhere to DOAC and for patients with aPL syndrome.[128] For patients with high-risk aPL syndrome, INR should remain between 2 and 3. These patients should not be transitioned to DOAC because DOAC-treated aPL patients have a higher risk of recurrent thrombosis.[97] For aPL patients with arterial thrombosis, target INR can be increased to 3 to 4. Low-risk aPL patients who have been started on a DOAC may remain on a DOAC if no complications have occurred.[97] Given warfarin is contraindicated in pregnancy, aPL pregnant females should be transitioned to a low-dose aspirin and prophylactic heparin. If the pregnant patient has a history of thrombotic aPL syndrome, then therapeutic heparin and low-dose aspirin should be started. Patients prescribed warfarin who experience warfarin-induced skin necrosis should be treated immediately. Treatment begins with immediate withdrawal of warfarin. Next, parenteral anticoagulation can be given as well as vitamin K and/or FFP.[120] If warfarin-induced skin necrosis is secondary to protein C deficiency, monoclonal antibody-purified concentrates of protein C can be administered.

Special consideration should also be taken in patients with antithrombin deficiency or COVID-19 and pregnant patients with FVL, prothrombin mutation, or antithrombin deficiency. Patients with antithrombin deficiency derived from inherited or acquired states may display resistance to heparin products, defined as inadequately increased aPTT values despite robust efforts at anticoagulation (using >35,000 units of heparin daily).[9] To anticoagulate these patients, they can receive a DOAC or be given antithrombin replacement therapy. Antithrombin replacement therapy induces sensitivity to heparin products and is particularly

TABLE 100.6 Caprini Risk Assessment

Risk Factor Representing 1 Point

Age 41–60 years
Minor surgery
Recent events <1 month: major surgery, CHF, sepsis, pneumonia
Venous disease or clotting disorder: varicose veins, current swollen legs
Infant that is premature with toxemia or growth restriction
Medical patient on bed rest
Past medical hx: BMI >25, acute MI, COPD, other risk factors
COC or HRT
Pregnancy or postpartum

Risk Factor Representing 2 Points

Age 61–74 years
Type of surgery: major >45 min, laparoscopic >45 min, or arthroscopic surgery
Recent events <1 month: immobilizing plaster cast
Current central venous access
Patient confined to bed > 72 hours
Present or previous malignancy

Risk Factor Representing 3 Points

Age ≥75 years
Venous disease or clotting disorder: history of DVT/PE, family hx of thrombosis, positive FVL, elevated serum homocysteine, positive LA, elevated anticardiolipin antibody, HIT, other congenital acquired thrombophilia
Hx of unexplained stillborn infant, recurrent spontaneous abortion

Risk Factor Representing 5 Points

Type of surgery: elective major lower extremity arthroplasty
Recent events <1 month: hip, pelvis or leg fracture, stroke, multiple trauma, acute spinal cord injury causing paralysis

Recommended Prophylaxis[a]

SCORE (RISK)	MANAGEMENT
0–4 (low-moderate)	Early ambulation
5–8 (high–very high)	Early ambulation, intermittent pneumatic compression + 7–10 days anticoagulation,
> 9 (highest)	Intermittent pneumatic compression + 30 days anticoagulation

Points allocated to risk factors addressed in the Caprini Risk Assessment and the recommended prophylaxis in postoperative surgical patients. Anticoagulation options include unfractionated heparin or low-molecular-weight heparin.

[a] Recommended prophylaxis not including patients undergoing total joint replacement. Recommendations for total joint replacement include the following: score of <10—early ambulation, intermittent pneumatic compression, and aspirin for 30 days postoperatively; score >10—early ambulation, intermittent pneumatic compression, and anticoagulation (low-molecular-weight heparin or fondaparinux or direct oral anticoagulation [DOAC]) for 30 days postoperatively.

BMI, Body mass index; *CHF,* congestive heart failure; *COC,* combined oral contraceptive; *COPD,* congestive obstructive pulmonary disease; *DVT,* deep vein thrombosis; *FVL,* factor V Leiden mutation; *HIT,* heparin-induced thrombocytopenia; *HRT,* hormonal replacement therapy; *hx,* history; *LA,* Lupus anticoagulant; *MI,* myocardial infarction; *PE,* pulmonary embolism.

From Cronin M, Dengler N, Krauss ES, et al. Completion of the updated Caprini Risk Assessment Model (2013 version). *Clin Appl Thromb Hemost.* 2019;25:1076029619838052.

helpful in patients who are going to the operating room and need rapid discontinuation of anticoagulation for mitigation of bleeding risk. If the decision is to anticoagulate with a DOAC, plasma antithrombin activity should be repeated for confirmation during the transition away from heparin. Furthermore, these patients should be discharged on therapeutic anticoagulation and followed up by hematology.[129] Patients with COVID-19 are at risk for both macrothrombotic events (DVT, PE) and immunothrombosis. Non–critically ill hospitalized COVID-19 patients should receive *at least* standard-dose thromboprophylaxis, using LMWH or unfractionated heparin. However, therapeutic-intensity LMWH or unfractionated heparin demonstrated a decreased risk of major thromboembolic event or death, suggesting therapeutic intensity may be preferred over standard dose in non–critically ill COVID-19 patients.[131] Meanwhile, critically ill COVID-19 patients should receive standard-dose thromboprophylaxis instead of therapeutic dosing. If COVID-19 patients who meet criteria are discharged on anticoagulation, they should receive rivaroxaban 10 mg daily for 35 days.[131] COVID-19–positive patients who develop VTE should be treated with anticoagulation for 3 to 6 months, in accordance with guidelines for VTE with a transient provoking risk factor. Our last special consideration includes pregnant patients with FVL, antithrombin deficiency, or PTM. These pregnant patients are at increased risk of recurrent pregnancy loss. Although no guidelines are available, studies have demonstrated that these patients may benefit from treatment with LMWH or unfractionated heparin, with or without aspirin.[132]

Medical Management—Role of Antiplatelets

Antiplatelet therapy is indicated for primary or secondary prevention of arterial disease, including acute ischemic stroke, MI, or peripheral arterial disease (see Table 100.3). For individuals with inherited thrombophilia, guidelines recommend aspirin in addition to heparin for pregnant patients with aPL syndrome.

Antiplatelet therapy has also been investigated in pregnant patients with FVL, antithrombin deficiency, or PTM who experience recurrent pregnancy loss. However, the results are debatable, with no guideline specifically endorsing the addition of aspirin to mitigate pregnancy loss in these patients. Antiplatelet therapy has also been investigated in prophylaxis for COVID-19 VTE. Randomized controlled trials (RECOVERY, ACTIVE-4a) demonstrated that the use of antiplatelet therapy (aspirin or ticagrelor) plus therapeutic-intensity heparin provided no difference in thromboembolic outcomes compared with therapeutic heparin alone.[131] In this section, we briefly discuss commonly used antiplatelets for the inherited or acquired risk factors for thromboembolism, which include aspirin, clopidogrel, and ticagrelor.

Aspirin exhibits its effects by irreversibly inhibiting cyclooxygenase (COX), thereby reducing platelet aggregation by inhibiting the synthesis of thromboxane A2.[133] Restoration of thromboxane A2 levels requires platelet turnover, which takes approximately 10 days. Aspirin has been recommended by the American Heart Association and American Stroke Association as the primary protective agent in cardiovascular disease in patients with a 10-year cardiovascular risk score above 10%.[133] Aspirin treatment failure, defined by vascular events during treatment, has been described in the literature with a frequency of 12.9%. Failure can be explained by poor medication adherence, poor absorption, drug interactions, insufficient dosing, and alternate pathways of platelet activation. Alternate pathways include upregulation of COX expression during times of inflammation and polymorphisms of COX, platelet membrane glycoproteins, the *P2Y1* gene, and/or vWF.

Clopidogrel (brand name Plavix) is a second-generation thienopyridine antiplatelet agent that reduces platelet aggregation by irreversibly inhibiting the $P2Y_{12}$ ADP receptors on the surface of platelets.[133] Subsequently, ADP-mediated activation of the glycoprotein IIb/IIIa complex is prevented. The benefits of clopidogrel have been demonstrated in multiple RCT. For example, clopidogrel has been shown to be more efficacious than aspirin in preventing adverse cardiovascular outcomes (Clopidogrel Versus Aspirin in Patients at Risk of Ischemic Events [CAPRIE] study) and beneficial when added to aspirin (dual-antiplatelet therapy) in patients with acute coronary syndrome (Clopidogrel in Unstable Angina to Prevent Recurrent Events [CURE] trial).[134] When ingested, clopidogrel starts as a prodrug and therefore requires metabolization to activate. Metabolism is mediated by the hepatic cytochrome P450 system. Hyporesponders or resistance to clopidogrel has been linked to genetic polymorphisms in the cytochrome P450 enzyme. Currently, the American College of Cardiology/American Heart Association guidelines state there is no randomized evidence to support routine genetic testing; however, the decision to perform genotyping can be made on a selective basis.[134]

Ticagrelor reversibly binds to and inhibits the $P2Y_{12}$ platelet receptor. This drug is approved for the prevention of cardiovascular events in patients with atherosclerotic cardiovascular disease and may be beneficial in patients with clopidogrel resistance. In additional to its antiplatelet activity, ticagrelor has known antiinflammatory properties.[135] Particularly, ticagrelor-treated patients have demonstrated reduced risk of infection-related death and improved lung function in patients hospitalized with pneumonia.

Surgical or Endovascular Management

Acute thromboembolism has the potential to be managed through surgical or endovascular interventions. Management of thrombosis depends on type of thrombosis, anatomic location, extent of disease, and hemodynamic status of the patient. Treatment options include medical anticoagulation, surgical embolectomy, catheter-based interventions using fibrinolytic agents, percutaneous mechanical thrombectomy or pharmacomechanical thrombolysis, endovascular stenting, and/or systemic thrombolysis. In this section, we discuss fibrinolytics.

Fibrinolytic agents use plasminogen activators to activate plasmin. Activating plasmin leads to the cleavage of cross-linked fibrin, thereby dissolving the clot. There are three generations of plasminogen activators, which include streptokinase, urokinase, alteplase, reteplase, and tenecteplase.[136] Streptokinase and urokinase are both considered to be first-generation fibrinolytic agents. Unfortunately, the first-generation fibrinolytics lack fibrin specificity because they bind circulating systemic plasminogen and fibrin-bound plasminogen with similar affinity. Given this lack of affinity and streptokinase's high risk of allergic reactions in patients, these fibrinolytics have limited use. Alteplase, on the other hand, is a second-generation agent enzymatically manufactured to resemble t-PA, making it fibrin specific. By localizing to plasminogen on fibrin, there is a reduced risk of digestion of systemic soluble fibrinogen. Lastly, the third-generation agents, tenecteplase and reteplase, are modified versions of enzymatically manufactured t-PA with increased specificity to fibrin. The half-life of these third-generation agents is longer because they have been modified to evade binding of PAI-1 and therefore require reduced dosing. Absolute contraindications to the use of these various systemic fibrinolytics include active bleeding, prior history of intracerebral hemorrhage, brain or spinal surgery within the past month, ischemic stroke within the past 3 months, suspected aortic dissection, cerebrovascular disease or central nervous system neoplasia, recent head trauma with fracture or brain injury, and abdominal surgery (Table 100.7).[136]

FXa	Activated factor X	VTE	Venous thromboembolism
FXI	Factor XI	vWD	von Willebrand disease
FXIa	Activated factor XI	vWF	von Willebrand factor
FXII	Factor XII		

CONCLUSION

In conclusion, bleeding or thrombosis intraoperatively or postoperatively is a result of the complex interplay between coagulation enzymes, platelets, endothelial cells, and even immune cells. Understanding the molecular mechanisms in the hemostatic system is necessary to elucidate whether pathologic bleeding or thrombosis is related to inherited or acquired disorders. By understanding the mechanism of the disorder, an effective medical or surgical intervention can be used.

CHAPTER 101

Contemporary Management of Carotid Disease

Rohini J. Patel, Jesse A. Columbo, David H. Stone, and Mahmoud B. Malas

OUTLINE

Introduction
Pathophysiology
Clinical Presentation
Diagnosis
  History
  Physical Examination
  Surveillance Versus Intervention
  Carotid Duplex Ultrasound
  Computer Tomography Angiography
  Magnetic Resonance Angiography
  Digital Subtraction Angiography
Treatment
  Medical Therapy
  Carotid Endarterectomy
Transfemoral Carotid Artery Stenting
  Considerations
  Technique
  Perioperative Complications
  Transcarotid Artery Revascularization
  Technique
  Postoperative Care
  Perioperative Complications
Long-Term Follow-Up and Complications
  Follow-Up
  Restenosis
Nonatherosclerotic Carotid Disease
  Fibromuscular Dysplasia
  Carotid Dissection
  Carotid Aneurysm

INTRODUCTION

Carotid artery stenosis remains a major underlying risk factor for stroke, which is the fifth-leading cause of death in the United States.[1] Currently, it is estimated that extracranial carotid occlusive disease affects approximately 1.5% of individuals worldwide, with increasing prevalence among older patients.[2] Risk factors that predispose toward carotid artery stenosis are those commonly associated with atherogenesis and peripheral arterial disease, including smoking, hypertension, dyslipidemia, and diabetes.[3] In this setting, the American Heart Association (AHA) currently recommends ongoing surveillance for patients with moderate carotid stenosis and consideration of revascularization for those with severe disease.[4] Consequently, approximately 100,000 carotid artery interventions are performed annually in the United States alone, with many more patients followed on a longitudinal basis.[5]

PATHOPHYSIOLOGY

Evidence of early-stage atherosclerotic arterial disease can be detected as early as the third decade of life.[6,7] Damage of the arterial intima by free radicals or lipoproteins leads to fatty streak formation, the precursor to an arterial plaque.[8] Areas of the arterial tree that are subject to turbulent blood flow, such as the carotid artery bifurcation, are particularly prone to plaque formation.[9,10] Infiltration of lipoproteins, accompanying proinflammatory cytokines, and turbulent blood flow at such anatomic locations collectively predispose to the physiologic environment where an atherosclerotic plaque may develop.[8,11] Over time, such plaque formation can evolve to frank luminal encroachment with ensuing arterial stenosis or occlusion.[11] For the carotid artery in particular, plaque formation can additionally serve as a nidus for thrombus formation, placing a patient at risk for thromboembolic complications, such as transient ischemic attack (TIA) or stroke.[12,13]

CLINICAL PRESENTATION

The clinical presentation for patients with carotid artery stenosis has historically been divided into symptomatic and asymptomatic disease. Symptomatic carotid stenosis is commonly defined as a patient who has experienced amaurosis fugax (transient monocular blindness), cortical TIA, or stroke within the 6 months before presentation, thought to be attributable to an ipsilateral carotid lesion. This definition is predicated on landmark randomized controlled trials (RCTs) that form the historical foundation for current evidence-based guidelines on the management of extracranial carotid disease.[14,15] Accurate designation of patients as either asymptomatic or symptomatic remains a critical diagnostic distinction with requisite therapeutic sequelae, most notably including the thresholds and benefits of revascularization, based on the presence or absence of adjudicated focal neurologic symptoms.[4]

Patients can be diagnosed with asymptomatic carotid disease in a variety of ways. Notably, the United States Preventative Services Task Force does not currently recommend routine screening for asymptomatic carotid disease, and consequently, most asymptomatic disease is detected on studies performed for alternative indications.[16] Deviations from this guidance occur not uncommonly and often transpire in the setting of an audible neck bruit, documented multifocal vascular disease, or the presence of multiple atherosclerotic risk factors. However, even under these considerations, most asymptomatic carotid disease is detected incidentally in current practice.

The presentation and diagnosis of patients with symptomatic carotid disease is accordingly more urgent. Patients with thromboembolic complications from an underlying associated carotid stenosis, including amaurosis fugax, TIA, or stroke, will commonly present acutely to the emergency room or clinic for urgent evaluation. Symptoms that resolve within 24 hours are historically categorized as TIA, whereas those lasting beyond this time interval or remaining beyond this interval are consistent with a stroke. Likewise, radiographic abnormalities on dedicated cerebral imaging such as magnetic resonance imaging (MRI) may confirm a diagnosis of stroke. As may be expected, TIA and stroke symptoms can vary widely in their severity. Patients with less severe symptoms may not always present to an emergency room for evaluation. Rather, some may present less acutely to their primary care provider, as may often be the case among patients with vision changes that may not be immediately apparent as amaurosis fugax. In other situations, patients may initially present to an ophthalmologist or other vision professional, which may subsequently prompt further evaluation of the carotid arteries. Although it may initially seem that the diagnosis of symptomatic carotid stenosis would be straightforward, a high index of clinical suspicion is paramount, considering the wide range of possible symptoms.

DIAGNOSIS

Carotid artery disease is diagnosed through a combination of the clinical history and physical examination in combination with imaging findings. The next part of this chapter focuses on the diagnosis of carotid artery atherosclerotic disease.

History

A thorough history is elucidated from the patient. This includes medical history, such as atrial fibrillation, which can make a patient more susceptible to a TIA or stroke. The Vascular Quality Initiative defines *history of neurologic event* as either stroke or TIA in the right or left eye, cortex, or vertebrobasilar region.

Physical Examination

Carotid artery disease can be identified by listening for a bruit on examination. A bruit is the sound of turbulent blood flow in a vessel and can be recognized on physical examination with a stethoscope. In patients with carotid artery stenosis, the luminal narrowing causes turbulent blood flow. However, not all diseased arteries produce a bruit, especially the ones with critical stenosis not allowing enough blood to flow through to cause turbulence (false-negative bruit). One the other hand, you could hear a bruit from a stenotic external carotid artery (ECA; false-positive bruit). Thus, it is important to correlate examination findings with imaging.

Surveillance Versus Intervention

Once the diagnosis of carotid artery stenosis has been established, the next decision is whether the patient should be medically managed with surveillance versus an intervention with an invasive procedure. This varies by degree of luminal stenosis as well as symptomatic status of the patient.

For symptomatic patients who present within 6 months of a stroke, TIA, or amaurosis fugax, a workup to assess for carotid artery disease is performed. Initial presentation relies on carotid duplex ultrasound as a quick, efficient, and reliable method to diagnose carotid disease. Adjuncts to carotid duplex that will be discussed include computed tomography angiography (CTA), MRI/magnetic resonance angiography (MRA), and traditional angiography. Each modality has its own benefits and risks associated.

The threshold for intervention in both asymptomatic and symptomatic patients has been well studied, and guidelines have been created by the Society for Vascular Surgery as clinic practice guidelines for the management of extracranial cerebrovascular disease.[17] Level 1B evidence supports surgical intervention in combination with maximum medical therapy as opposed to medical therapy alone for individuals with asymptomatic carotid artery disease and greater than 70% stenosis. This comes from the results of RCTs, including both the Asymptomatic Carotid Atherosclerosis Study (ACAS) and the Asymptomatic Carotid Surgery Trial (ACST).[14,18] These RCTs found that combined stroke and death at 5 years in those who underwent carotid endarterectomy (CEA) for asymptomatic ≥60% stenosis was 4.1% compared with 10% in those who underwent medical therapy alone.

For symptomatic patients, guidelines are based on two RCTs, the European Carotid Surgery Trial (ECST) and the North American Symptomatic Carotid Endarterectomy Trial (NASCET). Both these trials found that for symptomatic patients with less than 50% stenosis, surgical intervention with CEA did not decrease the rate of future neurologic events compared with medical therapy alone.[19,20] However, for symptomatic patients with over 50% luminal stenosis, both the ECST and NASCET RCTs have found a benefit in CEA over maximal medical therapy alone. NASCET demonstrated that symptomatic patients with ≥70% stenosis have a 9% risk of stroke at 2 years compared with a 26% risk in the group with medical therapy alone.[20]

Regardless of symptomatic status, a patient's true degree of luminal stenosis must be ascertained before determining an intervention plan—whether this be surgical or medical therapy. The next part of this chapter focuses on the various modalities available to vascular surgeons to identify carotid artery disease.

Carotid Duplex Ultrasound

Duplex ultrasound is a relatively fast, cost-effective, and easy way to assess a patient's carotid artery in the outpatient setting, at inpatient bedside, or in the emergency department (Fig. 101.1). This modality was proven to be effective in the United Kingdom Health Technology Assessment meta-analysis in 2006, which found that duplex ultrasound should be used as a first-line imaging modality to identify patients with 70% to 99% internal carotid artery (ICA) stenosis, but that benefit is less prominent in patients with 50% to 69% stenosis.[21]

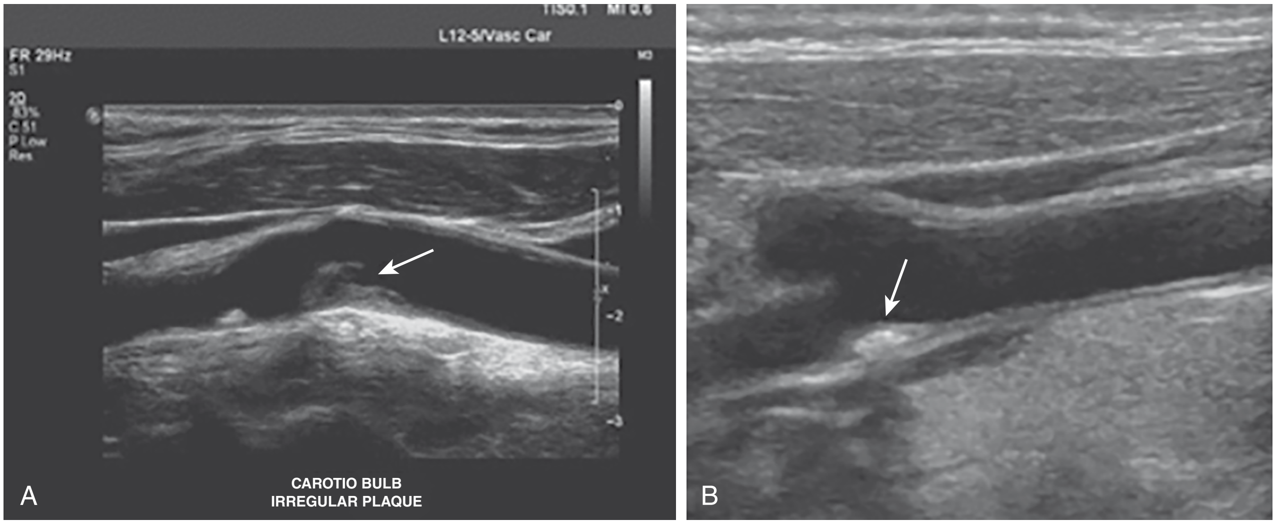

FIGURE 101.1 (A–B) Duplex ultrasound with plaque *(arrows)* in carotid artery. (From Al-Nouri O, Malas MB. Cerebrovascular disease. In: Dimick JB, ed. *Mulholland and Greenfield's Surgery Scientific Principles & Practice*. 7th ed. Philadelphia: Wolters Kluwer; 2021.)

Carotid duplex diagnosis of ICA stenosis is shown in Table 101.1. The findings in Table 101.1 have been proven and supported by the idea that duplex ultrasound can be used to diagnose greater than 70% stenosis.[22] According to the Society for Vascular Surgery, screening the base population of asymptomatic individuals is not recommended unless the individual has significant risk factors for carotid artery disease.[17]

Overall, the biggest limitation of carotid artery duplex ultrasound is the operator's skill and experience. When measuring the carotid artery, the information is delivered using either the ECST or the NASCET. The ECST multicenter RCT involved 3200 patients; percentage of stenosis was measured from the estimated original diameter at the site of the stenosis minus the narrowest ICA diameter divided by the estimated original diameter.[23] On the other hand, NASCET estimated percentage of stenosis from the normal distal cervical ICA minus the narrowest ICA diameter divided by the distal ICA diameter.[24] This historically was determined from angiographic data, whereas duplex is based on velocity, however, correlated to angiographic definitions.

Carotid duplex ultrasound provides an efficient means of carotid artery disease and is able to be incorporated into many medical settings. Although operator ability is the biggest drawback, its advantages, including cost and speed of use, have allowed many patients to be both surveilled over time as well as expeditiously transitioned from medical management to surgical treatment based on the results. It is critical to have well-trained technologists who are certified to do arterial studies and not only gray-imaging ultrasound and are supervised by certified vascular surgeons. One of the limitations of duplex ultrasound is its inability to penetrate through calcified lesions, which could mask high-grade stenosis.

Computed Tomography Angiography

CTA of the head and neck can also be used to diagnose carotid artery disease. CTA scans involve an intravenous administration of a contrast agent followed by a spiral CT scan and, in the head and neck region, can identify carotid artery disease both in an extracranial and intracranial location. CTA has been found to mimic the results of luminal stenosis found on duplex ultrasound; however, it has less reliability when distinguishing moderate and severe stenosis.[25]

One of the strongest benefits of the use of CTA imaging is the ability to image and assess the soft tissue, bony structures, and vasculature simultaneously in a quick and efficient manner. CTA also provides imaging of the aortic arch, for example, tortuosity, aberrant anatomy, and degree of calcification. CTA also provides valuable information on lesion length, extent, and level of disease to identify high lesions not amendable to standard CEA. It allows identification of tandem lesions distally as well as proximal common carotid artery (CCA) orifical lesions at the arch—both of which can increase the risk of CEA and might change the surgical plan. In our practice, we routinely evaluate the circle of Willis to understand cerebral collateral flow. This is important in planning a shunt for CEA and flow reversal for transcarotid artery revascularization (TCAR). Limitations of CTA involve contrast exposure

TABLE 101.1 Carotid Duplex Diagnosis of Internal Carotid Artery (ICA) Stenosis

PERCENTAGE STENOSIS	ICA PSV (cm/s)	PERCENTAGE PLAQUE	ICA/CCA PSV (RATIO)	ICA EDV (CM/S)
Normal	<125	None	<2	<40
<50	<125	<50	<2	<40
50–69	125–230	≥50	2–4	40–100
>70	>230	≥70	>4	>100

CCA, Common carotid artery; *EDV,* end-diastolic velocity; *PSV,* peak systolic velocity.

for those with chronic kidney disease, radiation exposure, and cost compared with duplex ultrasound.[26] Additionally, patients with intravenous contrast allergy are unable to undergo a CTA. Given these limitations, the Society for Vascular Surgery has determined level 1B evidence for duplex over CTA in the screening modality for asymptomatic individuals.

CTA imaging is an important adjunct when patients are being planned for carotid artery stent (CAS). This is because of the valuable information obtained from the aortic arch to the circle of Willis involving vessel anatomy.[26] Additionally, in small-volume analyses, CTA was found to be helpful in assessing carotid plaque morphology and identifying both geometry and tissue composition.[27] The overall use for plaque characteristics is yet to be determined, but it could pave an avenue toward identifying high- and low-risk patients based on more than luminal stenosis.

Magnetic Resonance Angiography

MRA imaging can be obtained to identify carotid artery disease as well. MRA has been found to have high sensitivity and specificity, but with high variation in quality of studies. Additionally, the time for completion can be a limiting factor; however, software improvements have led to increased use for diagnosis.[28] MRA is advantageous because it avoids radiation exposure to the patient and does not require complex postprocessing to account for bony structures. MRA currently does not have a role in screening for carotid disease because of the cost.

As an adjunct tool, MRA can identify vessel anomalies, but occluded vessels or calcification is not well elucidated.[26] However, plaque morphology using MRA has been found to be helpful for monitoring the fibrous cap and lipid core.[29] Additionally, MR detection of intraplaque hemorrhage has been used to predict recurrent ischemia, stroke, and embolization after CEA.[30,31] MRA, however, cannot be performed in individuals with metal implants or those who are easily claustrophobic.

Digital Subtraction Angiography

Conventional angiography, or digital subtraction angiography (DSA), had been considered the gold standard for carotid artery disease identification. However, it can come with added risks. A review of almost 20,000 patients found that 2.6% of patients had a neurologic complication, and 4% had an access site hematoma; the increased risk was found to be related to atherosclerotic disease, frequent TIA, and intracranial hemorrhage (subarachnoid).[32] Currently, these is no role for routine DSA as a diagnostic tool because of the improved imaging capability of both CTA and MRA. Limitations to DSA include risk of radiation exposure and patients with contrast allergy. The only indication is two conflicting studies comparing duplex ultrasound and CTA, in which case one found DSA to be the most accurate method to confirm the degree of stenosis.

TREATMENT

Medical Therapy

All patients with carotid disease, both symptomatic and asymptomatic, should receive optimal medical therapy. Once the diagnosis of underlying carotid occlusive disease is established, patients should be initiated on antiplatelet therapy, most commonly with daily aspirin.[4] High-intensity statin therapy has been demonstrated to reduce the long-term risk of stroke in patients with symptomatic carotid stenosis and should also be considered for asymptomatic patients based on their individual risk profile.[4,33]

Risk factor mitigation is also an important mainstay in the treatment of carotid artery stenosis. In addition to the management of dyslipidemia described earlier, several other risk factors warrant mentioning. Smoking cessation should certainly be strongly advised to all patients with active tobacco use.[34,35] Management of hypertension can both slow the progression of carotid disease and help to improve perioperative blood pressure management should revascularization be undertaken.[35] The management of diabetes, coronary disease, obesity, and pulmonary disease, among other comorbidities, remains integral to achieving optimal outcomes for patients.[4]

Carotid revascularization remains one of the most heavily studied procedures in vascular surgery, with more than a dozen randomized clinical trials investigating the efficacy of procedures versus medical therapy (Table 101.2) and comparing CEA to transfemoral stenting (Table 101.3). This high-quality evidence forms the foundation for clinical practice guideless by the AHA and Society for Vascular Surgery.[4]

TABLE 101.2 **Trials of Carotid Endarterectomy (CEA) Versus Medical Therapy**

TRIAL	YEAR	POPULATION	OUTCOME	ARM 1	ARM 2	RISK	ARR	RR
NASCET: high grade	1991	Symptomatic, >70%	Any ipsilateral stroke at 2 years	Aspirin	CEA	26% vs. 9%	17%	0.33
NASCET: moderate	1998	Symptomatic, 50%–69%	Any ipsilateral stroke at 5 years	Aspirin	CEA	22.2% vs. 15.7%	6.50%	0.7
NASCET: mild	1998	Symptomatic, <50%	Any ipsilateral stroke at 5 years	Aspirin	CEA	18.7% vs. 14.9%	$p = 0.16$	
ECST	1998	Symptomatic, >80% (ECST)	Major stroke or death at 3 years	Aspirin	CEA	26.5% vs. 14.9%	11.6%	0.56
ACAS	1995	Asymptomatic, >60%	Perioperative stroke/ death, ipsilateral stroke at 5 years	Aspirin	CEA	11.0% vs. 5.1%	6.9%	0.46
ACST	2004	Asymptomatic, >60%	Any stroke or perioperative death at 5 years	Aspirin ± statin	CEA	11.8% vs. 6.4%	5.4%	0.54
VA Trial	1993	Asymptomatic, >50%	Ipsilateral TIA or stroke under follow-up	Aspirin	CEA	20.6% vs. 8.0%	12.6%	0.39

However, despite the abundance of data to support carotid revascularization, there remains persistent debate surrounding its utility in achieving long-term stroke risk reduction. This stems primarily from advances in medical therapy that have been made since these trials were conducted. In fact, some experts now claim that the results of these seminal trials no longer apply and that surgical revascularization for asymptomatic patients is not necessary.[36] Conversely, proponents of surgical therapy continue to cite a high longitudinal risk of stroke among patients with severe carotid stenosis, despite their asymptomatic status.[37] Accordingly, there remains persistent controversy on how best to manage patients with carotid stenosis, particularly among those who are asymptomatic.

The Carotid Revascularization and Medical Management for Asymptomatic Carotid Stenosis Trial (CREST-2) seeks to add evidence to this growing debate. CREST-2 is two parallel trials that are enrolling patients with asymptomatic carotid stenosis and randomizing them to either intervention with CEA or transfemoral carotid artery stenting (TFCAS), or best medical therapy.[38,39] This trial, sponsored by the National Institutes of Health, will provide important results that will likely help to optimally define which patients will derive benefit from carotid revascularization in contemporary practice.

Carotid Endarterectomy

Considerations

CEA remains the historical gold-standard procedure for revascularization of the extracranial carotid artery. Since its first description in 1953, CEA has been tested in over a dozen RCTs and rigorously compared against best medical therapy and TFCAS among symptomatic and asymptomatic patients.[40–42] To date, it remains one of the most comprehensively studied procedures in vascular surgery.

The choice of carotid revascularization strategy remains contingent on several important factors. Currently, three primary therapeutic options exist. CEA is described in this section; TFCAS and TCAR are described elsewhere.[43] Before the development of TFCAS and TCAR, CEA was the only available carotid revascularization option. As such, CEA remains an option for most patients considered for revascularization. This is particularly prudent when considering TFCAS or TCAR in patients who may not be ideal for these stent-based therapies. Although these newer revascularization procedures may have nuanced benefits in certain clinical and/or anatomic situations, CEA remains a central component of the vascular surgeon's armamentarium in treating carotid occlusive disease.

There are some clinical indications where CEA may carry increased surgical risk. These include patients with hostile neck anatomy, such as those with a prior neck dissection, where the potential risk of cranial nerve injury is increased; patients with a tracheostomy, where wound infection rates may be higher; patients with a contralateral laryngeal nerve injury, where even the anticipated low risk of nerve injury could have a significant consequence; patients with anatomic disease extending above C2, which could make adequate surgical exposure technically difficult; and patients who cannot tolerate general or regional anesthesia. In these situations, patients may be considered for an alternate method of carotid revascularization.

Carotid Endarterectomy Technique

Anesthetic and support devices. CEA is most often performed under general anesthesia. Evidence suggests that local/regional anesthesia can also achieve similar outcomes in appropriate patients with an experienced anesthesia and surgical team.[44] Ultimately, the type of anesthesia that is administered should be selected at the discretion of the operating surgeon in collaboration with the attending anesthesiologist.

Commonly placed support devices include two peripheral intravenous lines for the administration of anesthetic and blood pressure management medications, an arterial line for invasive blood pressure monitoring and measuring anticoagulation parameters during the operation (e.g., the activated clotting time [ACT]), and a Foley catheter that may be removed at the end of the procedure.

Intraoperative blood pressure management is an important consideration that should be discussed with the anesthesia team. Clamping the carotid artery during endarterectomy will require the brain to rely on either contralateral and/or collateral circulation, or flow through a shunt if one is used. During this part of the operation, it is prudent to ensure that there is adequate perfusion pressure and be vigilant to avoid hypotensive episodes that could result in hypoperfusion to the brain or ischemic stroke. Preoperative and intraoperative communication between the surgeon and anesthesiologist on blood pressure goals as the operation progresses is critical for a successful outcome.

Positioning. Appropriate positioning is an important component of a successful CEA procedure because it can facilitate or hinder the exposure of the distal ICA. The patient should be positioned supine on the operating room table with both arms tucked at the patient's side. A gel shoulder support or rolled towel should be placed under the upper back at the level of the shoulder blades to facilitate neck extension. The patient should then have their neck rotated to the contralateral side. Depending on the flexibility of the patient's cervical spine, support for the head may be needed, using either additional towels, a gel pad, or both. A balance should be found that maximizes cervical spine extension and contralateral rotation, which will best facilitate the surgical exposure of the carotid artery.

It is the authors' preference to have the patient on an operating room table that articulates at the knees, hips, and neck. The "beach chair" position optimally facilitates the technical dissection/exposure. This position has the patient's knees slightly bent, hips flexed, and the neck extended. Securing straps are then placed around the patient to facilitate secure rotation to the contralateral side so that both the operating surgeon and assistant have optimal visibility of the surgical field. The neck should then be draped so that the sternal notch, angle of the mandible, and earlobe all remain visible.

Exposure of the carotid artery. An incision is made over the anterior border of the sternocleidomastoid muscle. The length of the incision is tailored to the extent of the carotid lesion and planned endarterectomy site. This can be lengthened during the procedure if the initial incision is inadequate. The platysma is next encountered and divided. Meticulous hemostasis should be kept throughout the incision and ensuing dissection. The robust lymphatic drainage and circulation to the tissues of the neck make the liberal use of electrocautery on the superficial tissues a useful option.

Next, the sternocleidomastoid muscle should be reflected laterally. The tissues medial and just overlying the muscle make up a bloodless plane that can be followed to the carotid sheath. Superficial branches of the external jugular vein can be ligated. Cranially, there is a superficial nerve that is often encountered in the subcutaneous tissue. This nerve provides sensory innervation to the upper neck. This can be divided, if necessary, but will cause a permanent area of sensory loss on the upper neck near the incision.

The internal jugular vein is next visible and should be carefully mobilized and gently retracted laterally. If a small venotomy is made during dissection, repair should be performed using polypropylene suture. The facial vein branch is often notable and frequently marks the level of the carotid bifurcation and can be used as an initial guide as to whether the length of the incision and exposure are sufficient. The facial vein should be divided with silk ties, and then the jugular vein is gently retracted laterally along with the sternocleidomastoid muscle. Commonly during dissection of the jugular vein, the surgeon will encounter the omohyoid muscle, which typically marks the inferior aspect of the surgical exposure. The muscle can either be retracted inferiorly, divided with electrocautery, or tied and cut.

The carotid sheath is incised sharply, exposing the carotid artery. It is most often easiest to identify the CCA in the inferior aspect of the surgical exposure. The authors prefer to doubly loop the CCA with a silastic vessel loop to aid in proximal inflow control and if a shunt is needed during the procedure.

The vagus nerve is frequently found posterior and lateral to the carotid artery but occasionally may be found on its anterior surface. Care should be taken not to injure the vagus nerve during the dissection and, ultimately, clamping of the artery. The vagus nerve can sometimes be confused with branches of the ansa cervicalis that lie over the carotid artery. Branches of the ansa cervicalis are generally smaller and can be ligated with impunity.

An important anatomic variant is a nonrecurrent laryngeal nerve, which appears as a large branch off the vagus nerve overlying the carotid artery (rather than in the chest, where it generally originates). Identifying the vagus nerve will help delineate whether any branches arise from it, allowing the surgeon to avoid injuring this anatomic variant.

The exposure then progresses cranially over the carotid artery. Care should be taken not to extensively manipulate the carotid bulb, especially in symptomatic patients, to avoid potential disruption of the carotid plaque and inadvertently causing an embolic event with manipulation. Dissection of the tissue near the carotid bulb can also result in profound bradycardia as a result of stimulation of the carotid baroreceptors. If this occurs, the surgeon may anesthetize the carotid bulb with a small amount of 1% lidocaine.

The carotid bifurcation is next identified, exposing both the external and internal branches. The ECA generally branches toward the face, whereas the ICA progresses cranially and posteriorly toward the skull base. The ICA can be carefully dissected sharply, freeing it from surrounding tissue. The hypoglossal nerve is often apparent and typically encountered in the more cranial extent of the exposure. Once identified, the hypoglossal nerve should be carefully preserved to avoid injury. During this part of the dissection, a fixed retractor to assist in cranial exposure is often very helpful.

Once the exposure is satisfactory, the surgeon can proceed with the endarterectomy. Before clamping, systemic anticoagulation should be administered, most commonly with heparin, if no allergy is present. ACTs can be targeted to reach 250 or 300 seconds, depending on the preference of the surgeon and institutional norms. Particularly for symptomatic patients, it may be prudent to administer anticoagulation earlier in the operation, during the time of dissection of the carotid bulb and ICA. This should be left to the discretion of the operating surgeon because it can increase bleeding in the surgical exposure during dissection.

Endarterectomy. There are two commonly used techniques to perform the endarterectomy. One uses a longitudinal arteriotomy and patch angioplasty closure. The other approach is an eversion endarterectomy.

Longitudinal arteriotomy and patch angioplasty. The most common method of CEA is endarterectomy and patch angioplasty closure. The authors prefer to use a combination of angled clamps for the common and ECAs and atraumatic cerebral aneurysm clips to control the ICA. The ICA should be clamped first to avoid any thromboembolic events from clamping the common or ECAs. An arteriotomy is optimally made in a disease-free segment of the CCA. Angled fine scissors are used to extend the arteriotomy on the anterolateral surface of the carotid onto the ICA, extending just past the disease so that the endarterectomy can be ended in healthy carotid artery.

With the carotid opened, the endarterectomy can be performed. A plane is most often developed in the arterial media, and care should be taken not to allow the remaining carotid wall to be too thin. An assistant can retract the carotid plaque with a forceps while the surgeon uses a plaque elevator to gently push the arterial wall away from the plaque.

With the plaque removed from the artery, the surgeon then inspects the endarterectomy site. If the distal end point on the ICA has residual disease or any evidence of a flap is present, then fine-tacking sutures with 7-0 polypropylene suture should be considered to secure any end points and prevent dissection after restoration of antegrade flow. Meticulous care should be taken to remove any remaining debris from the endarterectomized site to avoid the potential for thromboembolic complications once perfusion is restored.

With the endarterectomy complete, the artery can then be closed. Patch angioplasty, with either bovine pericardium, vein, or polytetrafluoroethylene, is most often performed (Fig. 101.2). For large or redundant ICAs, primary closure may be considered, although this risks restenosis of the carotid upon closure and should be reserved for unusually large arteries.

Eversion endarterectomy. A less common but useful reconstruction option is eversion endarterectomy. To perform this, after arterial clamping, the carotid is opened transversely at the base of the internal carotid. Once transected, the plaque is focally endarterectomized and subsequently everted from the ICA by invaginating the ICA on itself, allowing for the entire plaque to be removed across its extent. The carotid artery is then closed with running polypropylene suture.

Cerebral protection. There are a variety of modalities to ensure that the brain tolerates carotid clamping. Placing a shunt from the CCA to the ICA is the only method that preserves ipsilateral blood flow through the carotid artery. To perform this, after the arteriotomy has been created, a vessel shunt is placed from the common carotid to the ICA, and the vessel is either looped or clamped around the shunt. Shunt flow should be confirmed with a handheld Doppler. Other methods to ensure that the brain has adequate collateral circulation include intraoperative electroencephalogram (EEG); carotid stump measurement, whereby the back pressure of the ICA is determined with the external and CCAs clamped; and finally, local/regional anesthesia, whereby the patient is awake and able to be monitored in real time. If any of these cerebral monitoring techniques demonstrate impaired perfusion, a shunt can then be placed to restore flow to the ipsilateral ICA.

Completion imaging. Completion studies are often a useful adjunct to detect any technical deficiencies after the endarterectomy is completed and antegrade flow is restored. It is the authors' practice to perform a completion duplex ultrasound before reversal of anticoagulation. Duplex ultrasound offers the ability to measure the waveforms in the ICA, ensure low-resistance flow, and visualize any remaining mobile debris at the endarterectomy site with B-mode imaging. Large debris or high-resistance flow should prompt consideration to reopen the patch to inspect the endarterectomy site. Alternatively, conventional angiography can be performed to ensure the integrity of the reconstruction at the surgeon's discretion or if a dedicated duplex study is not available. In the absence of a completion imaging study, auscultating the distal ICA with a sterile handheld Doppler probe can help to reassure that there is requisite flow, although it has the potential to miss a more nuanced technical defect at the endarterectomy or clamp sites.

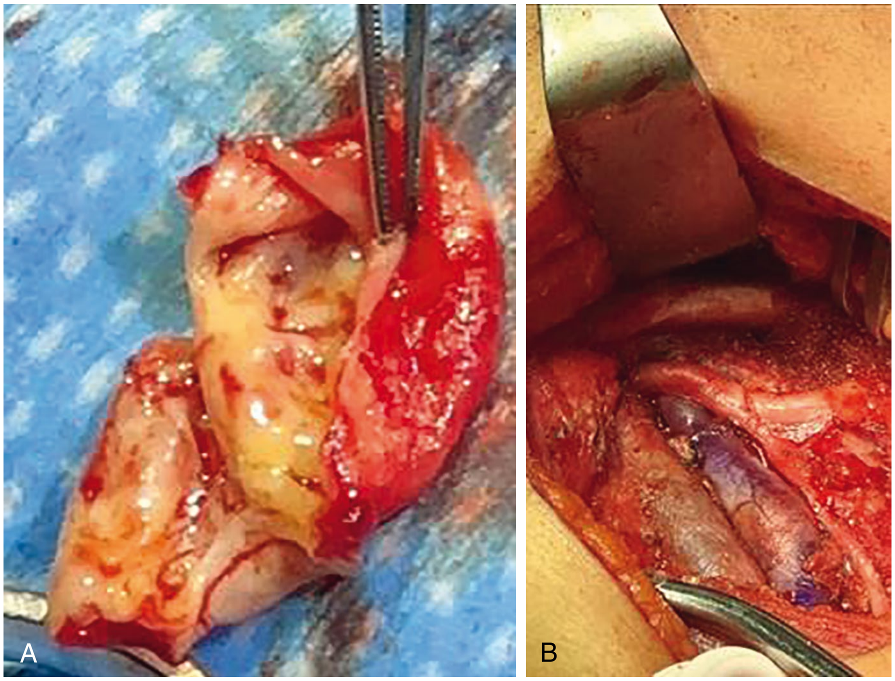

FIGURE 101.2 Carotid endarterectomy. (A) Endarterectomy sample. (B) Patch angioplasty.

Closure. After reversal of anticoagulation with protamine, hemostasis must be obtained at the patch and surgical field.[45,46] Additional polypropylene sutures can be used as needed, as well as topical hemostatic. When satisfied, the sternocleidomastoid can be approximated loosely to the more medial tissues. The platysma layer is then closed with braided absorbable sutures. The skin is then closed with absorbable monofilament suture. In patients who are on dual antiplatelet therapy (DAPT) or in whom there is a concern for hematoma development, a drain may be left in the surgical field at the surgeon's discretion.

Perioperative Care and Complications

Immediate postoperative course. After completion of the surgical procedure, the patient should be awakened from anesthesia in the operating room, and a neurologic examination should be completed before transferring the patient to the recovery unit. Dense hemiplegia with concern for intraoperative stroke should prompt immediate intervention. If no completion imaging was performed after arterial closure, then surgical reexploration should be considered. If completion imaging was performed, then immediate CTA may be considered versus reexploration to identify a potential source of the new-onset neurologic deficits.

If the patient's neurologic examination is back to baseline after extubation, then transfer to the recovery area is warranted. The recovery unit should be equipped to perform frequent neurologic and blood pressure monitoring via invasive measurements and intervene as needed. It is the authors' practice to keep patients in the postanesthesia care unit (PACU) for 4 hours before transfer to a regular ward bed if recovery has gone well. Practice patterns vary, and patients are commonly transferred to the intensive care unit (ICU) for their early recovery course. Patients may experience fluctuations in blood pressure postoperatively, and these should be managed with vasopressors or vasodilators as needed until the carotid baroreceptors have had the opportunity to reset, with corresponding normalization of the blood pressure. Refractory hypotension should prompt an evaluation for myocardial ischemia.

Most patients can expect an uneventful recovery course and discharge on postoperative day 1.

Perioperative stroke. The most dreaded perioperative complication is stroke. New neurologic symptoms in the immediate postoperative period should be quickly followed with a thorough workup for the etiology and neurologic consultation. Common etiologies include carotid thrombosis, distal dissection flap, or thromboembolism during the procedure. Each of these is potentially treatable, and prompt imaging with duplex ultrasound and/or CTA can guide an expedited intervention.

Neck hematoma. An expanding hematoma at the surgical site after CEA constitutes a potential emergency that can be life threatening. Reversal of anticoagulation during the procedure can reduce this risk but not eliminate it.[47] The surgeon must remain vigilant for neck hematoma, especially in the immediate postoperative course. Early symptoms include new hoarseness, shortness of breath, neck deviation, and of course, a new large palpable hematoma. Left untreated, an expanding neck hematoma can quickly lead to airway compromise and death.

Treatment of a neck hematoma therefore requires quick action. Clear communication with the anesthesiology team is paramount. If reoperation is required because of neck hematoma, intubation can be difficult as a result of tracheal deviation. Awake fiberoptic intubation is often advised by an experienced provider. The surgeon should be prepared to perform an emergent surgical airway if necessary, should the airway be lost during attempted intubation.

Once the airway is secured, the surgical incision can be reopened in a controlled fashion, and the hematoma is then evacuated. A meticulous inspection should then be conducted for the underlying etiology.

Acute coronary syndrome. The risk factors for carotid artery stenosis overlap substantially with those for coronary artery disease. As such, persistent hypotension, new angina, or an anginal equivalent should result in an immediate electrocardiogram, possible echocardiogram, and consideration of serum cardiac enzymes, with further interventions guided by the results of these studies in concert with cardiology consultation.

Reperfusion syndrome. Patients with severe carotid stenosis develop dilation of the cerebral vasculature to correct for the decreased flow across the carotid lesion. Once the carotid lesion is removed, it can take time for the cerebral vasculature to regain its normal vasoconstriction/vasodilation response to cerebral blood flow. It is difficult to predict how long it may take for the brain to regain this normal regulatory response. Unchecked cerebral blood flow into a very dilated arterial bed can lead to hyperperfusion, seizure, and cerebral hemorrhage, which carries a very high rate of mortality. It is therefore prudent to assess for this syndrome early and often. The first manifestation is often ipsilateral headache, although the headache can also be more generalized. Patients with headache after CEA should be fully investigated. Imaging options include transcranial Doppler, which can quantify the cerebral blood flow with established thresholds for reperfusion, or with noncontrast head computed tomography, which can evaluate for intracerebral hemorrhage. Any abnormalities should lead to close neurologic monitoring and meticulous blood pressure control, and discussion with a neurologist should be considered.

Transfemoral Carotid Artery Stenting

Considerations

TFCAS was initially approved for reimbursement by the Centers for Medicare and Medical Services (CMS) for high-risk medical or high-risk anatomic patients with symptomatic status and over 70% stenosis (Table 101.4). However, as of July 2023, CMS has released a proposed decision memo that approves TFCAS for the following: patients with symptomatic carotid artery stenosis greater than 50% stenosis and patients with asymptomatic carotid artery stenosis greater than 70% stenosis.[48]

If planning a TFCAS, careful review of preoperative imaging, including either CTA or MRA, must be undertaken to determine characteristics of the aortic arch (tortuosity, calcification, disease burden) and patency of the circle of Willis. Aortic arch characteristics can lead to excessive manipulation of the arch with wires and catheters that creates higher rates of embolization and stroke, of which type III arches are at highest risk.[49] Finally, TFCAS is contraindicated if any of the following are present: type III aortic arch, severely calcified arch, severely atherosclerotic arch, or 90-degree bends in the CCA or ICA. Stenting generally should be avoided in patients with unstable lesions, thrombus, or severe circumferential calcification.

There are several considerations that should be accounted for when planning for carotid artery stenting. A Cochrane review of 16 trials found that in patients over the age of 70 years, the rate of death or stroke was higher in TFCAS compared with CEA, and the review therefore recommends TFCAS in patients less than 70 years.[50] Additionally, a study using the Vascular Quality Initiative found that TFCAS stroke risk was related to age, whereas CEA was stable across age groups.[51] In terms of sex, a meta-analysis found no

TABLE 101.4 **Criteria for Transfemoral Stent**

MEDICAL CRITERIA—HIGH RISK	ANATOMIC CRITERIA—HIGH RISK
Age greater than 75	Contralateral carotid artery occlusion
Greater than 2-vessel coronary artery disease	Tandem stenosis greater than 70%
Unstable angina	Lesion above C2
New York Heart Association class III or class IV congestive heart failure	Restenosis after carotid endarterectomy
Left ventricular ejection failure less than 35%	History of neck radiation
Myocardial infarction in past 6 months	Decreased cervical spine mobility
Severe pulmonary disease	Tracheostomy
Contralateral recurrent laryngeal nerve injury	Previous neck surgery

difference in outcomes in TFCAS between males and females.[52,53] Treating combined carotid disease and coronary artery disease was assessed in a meta-analysis of 11 studies, which found no difference in death, stroke, or myocardial infarction (MI) based on timing between TFCAS and coronary artery bypass graft.[54] The overall goal of TFCAS is to stabilize the plaque against the vessel wall with the stent. Patients who are deemed candidates for TFCAS must be optimized with at least 1 week of aspirin and clopidogrel or other DAPT and statin therapy. A large national study has shown a reduction in mortality from stroke or MI after TFCAS if the patient was on statin therapy (11.4%) compared with nonstatin users (30.8%).[55]

Technique

TFCAS should be performed in a procedure room with high-quality imaging. An arterial line is placed by the anesthesia team to monitor intraoperative and postprocedural blood pressure. Prophylactic glycopyrrolate administration can be done because of the risk of bradycardia and hypotension. Other anesthesia concerns include access to vasopressor agents and local anesthesia technique. These procedures should be performed under local anesthesia to allow for neurologic monitoring through both speech and fine motor skills in the contralateral upper extremity. In addition, either EEG or transcranial Doppler can be performed. Given the high medical and anatomic risk with patients undergoing TFCAS, local anesthesia is necessary to frequently assess neurologic function and decrease cardiac complications in the perioperative period.[56]

Patients are placed supine with access to bilateral groins. Ultrasound guidance is used to obtain common femoral artery access with microneedle and sheath. Although less common, transbrachial or transradial access can be used. Upper extremity access is reserved for patients with a highly diseased aorta, and a large study found that if transbrachial or transradial access is necessary, it can have lower access site complications; however, it also has a higher risk of MI and technical failure.[57] Heparin is administered by anesthesia for a goal ACT between 250 and 300 seconds. We prefer to exchange our initial 5-Fr sheath for a 90-cm shuttle select 6-Fr sheath (Cook Medical, Bloomington, IL) parked in the descending aorta under fluoroscopic guidance. Angiogram is performed to evaluate the aortic arch with a 120-cm diagnostic catheter in the proximal descending thoracic aorta to perform an arch angiogram. The CCA is selected with one of the following catheters based on arch, innominate, and CCA anatomy: H1, JB1, JB2, Vert, VTK, or SIM. The catheter is placed proximal to the carotid bifurcation. The shuttle select sheath is telescoped over the catheter and wire to the mid-CCA. A carotid angiogram is then performed to identify the location of the stenosis, degree of stenosis, ECA patency, distal carotid artery flow, and ipsilateral intracerebral circulation.

The lesion is then crossed with an embolic protection device (EPD) placed in the distal ICA. With the EPD wire in place, rapid exchange is performed. Generally, the lesion is predilated with a balloon 3 to 4 mm smaller than the diameter of the artery. At this time, careful monitoring for bradycardia and hypotension must be undertaken. Balloon angioplasty is performed with slow inflation not to exceed 8 atmospheres, followed by immediate and slow deflation to minimize the embolic load. CASs are self-expanding and either straight or tapered with open or closed cells. Open-cell stents are conformable to tortuous anatomy or complex lesions, whereas closed stents have a decreased risk of embolization. However, data have shown no difference between closed- and open-cell stents in terms of stroke or death.[58,59] A multi-institutional study identified an increase in the risk of stroke with closed-cell stents if crossing the carotid bifurcation into the CCA.[60] The stent is sized 1 mm larger than the diameter of the CCA. The selected stent is advanced over the EPD wire and deployed to cover the entire lesion plus at least 5 mm proximal and distal to healthier vessels. It is our practice to use a 4-cm-long stent and extend it into the CCA on almost every patient to mimic CEA because we often extend the endarterectomy onto the CCA (Fig. 101.3). Postdilation has been found to be associated

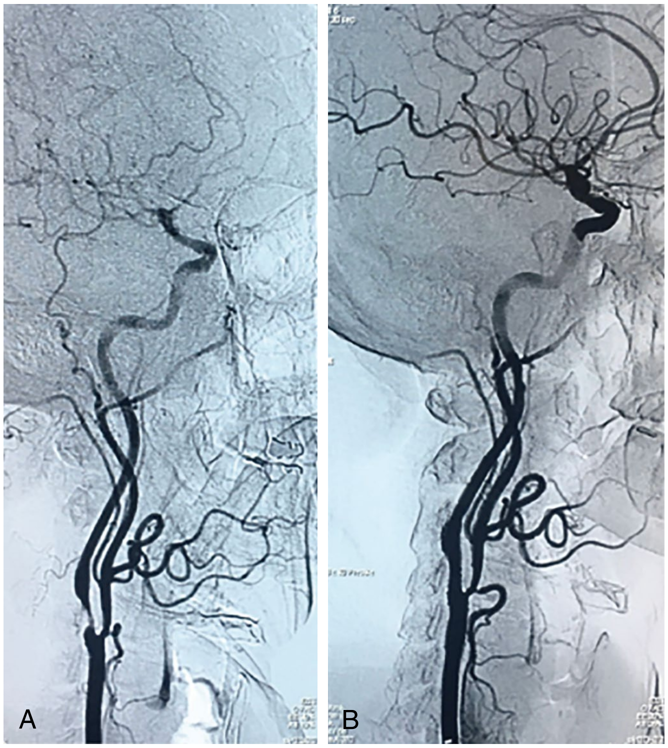

FIGURE 101.3 Transfemoral carotid artery stenting. (A) Prestent carotid angiogram. (B) Poststent carotid angiogram. (From Al-Nouri O, Malas MB. Cerebrovascular disease. In: Dimick JB, ed. *Mulholland and Greenfield's Surgery Scientific Principles & Practice*. 7th ed. Philadelphia: Wolters Kluwer; 2021.)

with increased risk of embolization, stroke/death, and hemodynamic instability.[61,62] It is our practice to postdilate only calcified and severely stenotic lesions with residual waste in the stent. Otherwise, these stents are self-expanding and will continue to expand postoperatively.[63] In patients who develop hypotension or bradycardia after dilation, they can be treated with volume expansion, atropine, or even vasopressor agents.

Completion cerebral angiogram is performed to confirm the absence of distal embolization and a patent stent. The EPD wire is retrieved, and the femoral access site sheath is removed with closure device deployment. Protamine can be administered per provider preference. There is no evidence of increased stroke with protamine administration, and we use it routinely to minimize the risk of access bleeding. The patient is then taken to the ICU for close monitoring of neurologic status and hemodynamics. Generally, patients are admitted for 24 hours and then discharged on aspirin and clopidogrel. Postoperative surveillance involves a duplex ultrasound within 6 weeks of the procedure, followed by 6-month ultrasound and then annually.

Perioperative Complications

Traditionally, the greatest complication after TFCAS is the risk of stroke. The introduction of EPDs has helped reduce the stroke risk. Initially introduced as a distal occlusion balloon, antegrade blood flow is stopped during stent deployment, and once deployment is complete, blood and embolic debris are suctioned endovascularly.[64] However, this has been abandoned because of distal ICA damage and plaque rupture as a result of the need to pass the lesion before balloon placement. These EPDs have largely been replaced with a filter. The filter allows antegrade blood flow, is passed across the lesion with a wire, and is recaptured with a filter-retrieval system. This leads to continuous cerebral blood flow, angiography access, and decreased manipulation of the carotid artery. However, there remains a risk of plaque disruption as a result of passing across the lesion before filter deployment. The final type of EPD is a proximal protection version, which deploys balloons in the common and ECAs to cause flow stasis, and intermittent syringe aspiration for debris. However, this device requires a larger 9-Fr sheath. The Prevention of Cerebral Embolization by Proximal Balloon Occlusion Compared to Filter Protection During Carotid Artery Stenting (PROFI) trial compared proximal balloon occlusion to filter and found that proximal occlusion had a lower incidence of ischemic lesions on MRI compared with filter; however, no significant difference in perioperative major adverse events was found.[65]

Many trials have compared the outcomes after TFCAS to CEA. The Stent-Protected Angioplasty Versus Carotid Endarterectomy (SPACE) randomized trial found that at 30 days, there were no significant differences in the rate of death or ipsilateral stroke between TFCAS or CEA, and as a noninferiority trial, the results do not support the widespread use of stenting.[66] The 2-year data for the SPACE trial again showed similar results; however, patients who underwent TFCAS compared with CEA were at higher risk of restenosis.[67] The results are further confirmed by the Endarterectomy Versus Angioplasty in Patients with Symptomatic Severe Stenosis (EVA-3S) randomized clinical trial, which found a 2.5 increased risk of stroke and death in the TFCAS versus CEA group.[68] Finally, the Carotid Revascularization Endarterectomy versus Stenting Trial (CREST) study found a higher rate of stroke in the TFCAS group but no difference between stroke and death at 10 years between TFCAS and CEA.[69,70] Table 101.3 summarizes the landmark randomized clinical trials comparing TFCAS to CEA.

Periprocedural stroke can be a result of arch or lesion embolization, EPD wire thrombosis, stent thrombosis, kinking, dissection, or hyperperfusion injury. Neuro-rescue techniques involve stent retrieval, aspiration thrombectomy, or catheter-directed thrombolysis. This is why it is critical to have the patient awake for neuromonitoring and when performing a cerebral angiogram before and after lesion treatment. Outcome of stroke can be dramatically improved with immediate recognition and rescue procedures. Additional complications include MI; however, CREST found lower rates of MI in TFCAS compared with CEA, likely because of lower rates of general anesthesia in TFACS.[69] Stent thrombosis has been identified in patients with densely calcified plaque and requires stent explantation and subsequent CEA.[71] Carotid dissections after stent placement are generally treated with either stent extension or antiplatelet therapy. Finally, because of groin access, complications can additionally include hematoma or infection and, in rare cases, fistula or pseudoaneurysm.

Transcarotid Artery Revascularization

Considerations

TCAR is a hybrid procedure that combines direct carotid artery access with stent placement. TCAR allows neuroprotection with flow reversal before any lesion manipulation. TCAR has several advantages over TFCAS by avoiding the atherosclerotic aortic arch and establishing CEA-like protection with clamping of the CCA, and TCAR has been found to have a lower learning curve than TFCAS, with most operators reaching technical proficiency after 10 to 15 procedures.[72] Similar to CEA and TFCAS, patients must first undergo medical therapy with dual antiplatelet agents, statins, antihypertensive medications, smoking cessation, and glycemic control.

TCAR was originally tested in Europe in 2009 with the Silk Road Medical Embolic Protection System: First-in-Man (PROOF) study, which found that TCAR had comparable embolic rates to CEA identified on diffusion-weighed MRI.[73] The safety of TCAR was confirmed in the Food and Drug Administration Investigation Device Exemption trial—Investigation of Transcarotid CAS With Dynamic Flow Reversal in Subjects With Significant Extracranial Carotid Stenosis (ROADSTER I). The stroke rates in this trial were 1.4% compared with 4.1% in TFCAS patients in the CREST trial. These data allowed TCAR to be approved in the United States in 2015.[74]

CMS requires that hospitals be enrolled in the Vascular Quality Initiative CAS registry as a condition for reimbursement. Patients are eligible for TCAR if they are symptomatic with greater than 50% stenosis of the carotid artery or asymptomatic with greater than 80% stenosis. Initially, at least one high-risk medical or anatomic criteria was required for TCAR eligibility (Table 101.5).

Additionally, certain anatomic criteria are needed in order to perform TCAR safely and need to be confirmed on duplex ultrasound and CTA. The CCA must be equal to or greater than 6 mm in diameter, the landing zone must be equal to or greater than 5 cm (defined as the distance between the clavicle and carotid bifurcation), the proximal CCA or access site should be free of calcification and significant atherosclerosis, and the ICA diameter should be between 4 and 9 mm. Additional criteria include a CCA depth of less than 4 cm from the skin surface and a ratio of the CCA depth to the clavicle-carotid bifurcation of less than 1. Patients undergoing TCAR must be on DAPT, including full-dose aspirin, clopidogrel, or other DAPT combination, in

TABLE 101.5 **Criteria for Transcarotid Artery Revascularization**

MEDICAL CRITERIA	ANATOMIC CRITERIA
Age over 75	Contralateral carotid artery occlusion
History of angina or greater than 2-vessel coronary artery disease	Tandem stenosis greater than 70%
Unstable angina	High cervical carotid artery stenosis
New York Heart Association class III or IV heart failure	Restenosis after CEA
Left ventricular ejection fraction less than 30%	Bilateral carotid artery stenosis
Myocardial infarction 72 hours to 6 weeks before procedure	Hostile neck
Chronic obstructive pulmonary disease with FEV_1 less than 50%	
Contralateral cranial nerve injury	
Renal insufficiency	

CEA, Carotid endarterectomy; *FEV_1*, forced expiratory volume in 1 second.

addition to a statin for at least 5 days before the procedure. It is our practice to test all patients for clopidogrel response, and if no adequate response is documented, the patient can be switched to another P2Y12 inhibitor.

Technique

One of the most unique features of TCAR is cerebral blood flow reversal, which allows neuroprotection. Additionally, direct cutdown and access to the carotid artery allow a stent to be placed without aortic arch manipulation. Neuroprotection is achieved when carotid blood and debris are shunted away from the brain through the carotid arterial sheath to the common femoral vein across an ENROUTE Flow Reversal System (Silk Road Medical, Sunnyvale, CA) that includes a filter and dual channels to allow for low- and high-flow reversal rates.[75] Flow reversal is achieved through the pressure gradient between the arterial and venous systems.

TCAR is generally performed in a room with high-quality imaging under either general, regional, or local anesthesia. There have been lower rates of reported MI with local or regional anesthesia compared with general anesthesia.[76] Similar to both CEA and TFCAS, an arterial line must be placed for close hemodynamic monitoring. Patients are positioned similar to CEA: supine with bilateral arms tucked in, a shoulder roll, and head/neck turned to the contralateral side. The procedure begins with an intraoperative ultrasound to confirm patent ICA, disease-free CCA, and distance between the clavicle and bifurcation.

An incision is made at the base of the neck to identify and isolate the CCA. The landmark for identifying the CCA is the triangular space between the sternal and clavicular heads of the sternocleidomastoid muscle (Fig. 101.4). A 3- to 4-cm segment of the CCA is isolated circumferentially, and a vessel loop or umbilical tape is placed proximally. Generally, a 5-0 Prolene suture is then used to create a purse string on the anterior surface of the CCA. Simultaneously, under ultrasound guidance, femoral vein access is obtained, and an 8-Fr venous sheath is placed for adequate flow reversal (Fig. 101.5).[75]

The patient is heparinized with a goal ACT of over 250 seconds. The Silk Road ENROUTE system includes an arterial sheath with dilator, venous sheath with dilator, flow controller with 200-um filter, 0.035 stiff guidewire, and floppy-tip wire. The set also

includes an 0.018 guidewire to mark when 3 to 5 cm of the wire is in the vessel, and a short 0.014 wire is used to deliver the stent.

Heparin is bolused based on weight (80 units per kg) and given intravenously to achieve an ACT between 250 and 300. Gentle traction with the vessel loop on the CCA is applied to superficialize the artery and allows a 21-gauge micropuncture needle access through the purse-string suture. It is imperative not to advance the microneedle into the back wall of the vessel to avoid dissection. It is our practice to advance the microwire under direct fluoroscopic visualization to ensure free movement and confirm luminal access. There are two techniques for access: (1) stop short of the bifurcation, and (2) engage the ECA (Fig. 101.6). The authors' preference is to engage the ECA whenever free of significant disease. This allows for more wire purchase when advancing the arterial sheath (10-Fr outer diameter) to avoid dissection. Less often, the lesion is at the bifurcation, or the ECA is severally diseased, requiring the "staying-short technique."

The microwire is advanced 3 to 4 cm into the CCA. The microsheath with dilator is advanced over the wire 2 to 3 cm into the CCA using the marking on the sheath. Pulsatile backflow after the wire and dilator are removed confirms proper positioning. An angiogram is performed to determine the location of the carotid bifurcation. We require at least a two-view angiogram to confirm intraluminal position of the sheath. If appropriate to engage the ECA, the wire is advanced 2 to 3 cm into the ECA with mask imaging guidance, followed by advancing the microsheath with the dilator. If the sheath is advanced without the dilator, there is a risk of dissection of the CCA. We like to perform another angiogram to ensure ECA selection. All angiograms should be hand-injected with 50% low-density contrast and 50% heparinized saline; a total of 4 to 6 cc is adequate. Care must be taken to inject the contrast gently to avoid embolization. Transcranial Doppler (TCD) has shown embolization even with contrast injection. A stiff wire is placed in the ECA through the microsheath. Advancing the stiff wire without sheath protection can cause dissection of the CCA. If stopping short, the same technique is used to get the stiff wire just proximal to the carotid bifurcation. We found that dilating the anterior wall of the CCA with the venous sheath dilatator helped advance the arterial sheath smoothly. Only 0.5 cm of the tip of the dilator is advanced into the anterior wall of the CCA with proper back tension on the wire. We prefer the incision to be along the longitudinal axis of the CCA and at least long enough to allow the operator to control the CCA directly after dilating the arterial hole with a two-finger hold on the wire. The Silk Road ENROUTE 8-Fr sheath is placed in the CCA over the wire and secured to the skin with silk sutures. The wire and dilator are withdrawn, and the arterial sheath is flushed gently with heparinized saline, ensuring no air in both the side port and connector. Next, the tubing is connected to the sheath and back-bled by holding the tubing up and then connected to the venous sheath in the common femoral vein to allow for passive flow reversal via a dynamic flow controller and filter. Two-view angiograms are performed to ensure an intraluminal position of the sheath.

Before proceeding, a specific TCAR time-out is performed. The time-out is performed to confirm adequate ACT; glycopyrrolate administration to prevent bradycardia and hypotension during lesion angioplasty; adequate mean arterial pressure to

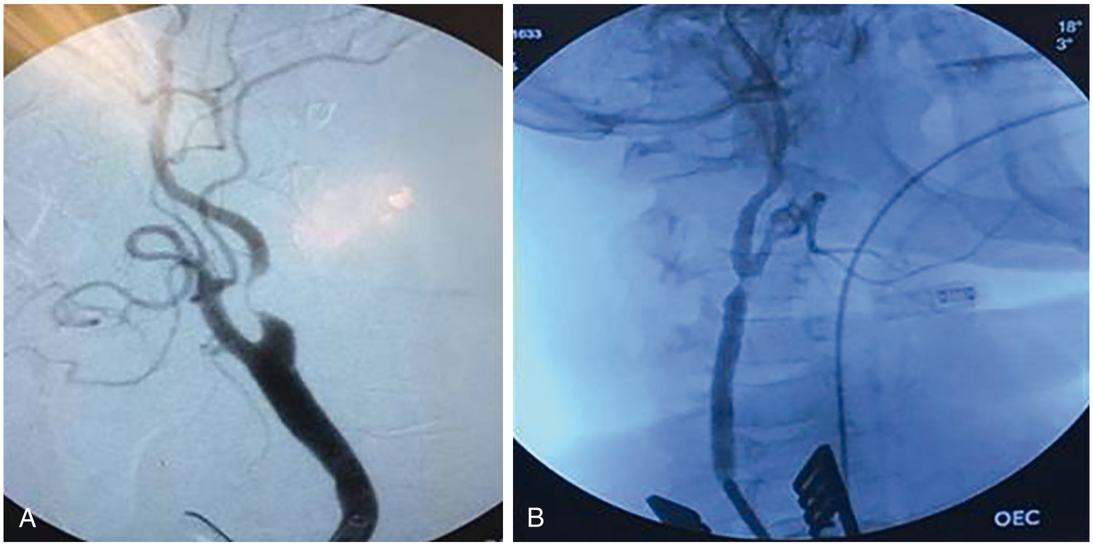

FIGURE 101.6 (A) When proximal external carotid artery (ECA) is free of disease, the engage-the-ECA technique is used. (B) When disease is present in distal common carotid artery or bifurcation, the stop-short technique is used.

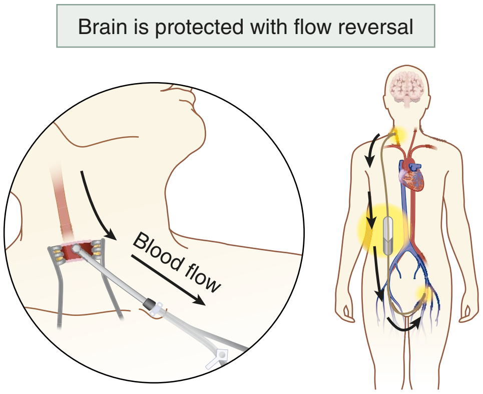

Brain is protected with flow reversal
Blood flow

FIGURE 101.7 Transcarotid arterial revascularization flow reversal. (Courtesy Silk Road Medical, Inc.; Silk Road Medical, Inc. retains and reserves all rights, including copyrights.)

achieve flow reversal; and wire, balloon, and stent preparation to minimize clamp time. The CCA is then clamped under direct visualization to avoid vagus nerve injury and achieve active flow reversal. We have avoided Rummel technique in clamping because it can cause vessel injury and have resorted to using atraumatic vascular clamps.

At this point, any debris from lesion manipulation is flushed from the carotid artery to the filter and trapped (Fig. 101.7). The blood is then returned through the femoral vein. Angiogram is performed to mark the bifurcation because the bed was moved to allow direct visualization of CCA clamping. The ICA lesion is then crossed with a 0.014 wire placed in the distal ICA. One advantage of the TCAR is the ability to use a curved catheter to help cross difficult lesions under flow reversal protection. This is more cumbersome with TFCAS with long distance for travel and all tortuosity applied to the catheter from a femoral approach through the iliacs, aorta, and arch. It is also more difficult to use guiding catheters to advance the wires, which are usually attached to an EPD. Once the lesion is crossed, we redilate with a 3- to 5-mm balloon. Slow and careful inflation and deflation of the balloon are performed, not exceeding 8 atmospheres. It is our preference to use smaller balloon in standard lesions and larger balloon in calcified lesions. The Silk Road ENROUTE stent is then delivered and deployed to cover at least 1 cm proximal and distal to the lesion (Fig. 101.8). An angiogram is then performed to confirm stent placement in the appropriate position. The stent is a nitinol self-expanding stent that is delivered through an 8-Fr sheath. The delivery system is 57 cm in length, and stent sizes include 20, 30, and 40 mm in length, with a diameter between 5 and 10 mm. The stent is sized 1 to 2 mm larger than the diameter of the CCA and tapers in the ICA. Poststenting dilation is debated; however, a study found that, unlike post dilation after TFCAS, post dilation in TCAR does not increase the risk of stroke but has a slight increase in the risk of TIA.[77] We tend to balloon calcified lesions where we see a significant residual stenosis of the stent. We always obtain multiple-view angiograms to ensure patency of the stent (Fig. 101.9).

IICA spasm can occur distal to the stent and, if not self-limiting, can be treated with nitroglycerin. Acute carotid occlusion is an emergency requiring treatment with oxygen, blood pressure support, and clot aspiration versus thrombolytic. In the case of dissection, an additional stent can be placed. The CCA is

CEA, Carotid endarterectomy; *MI,* myocardial infarction; *ROADSTER,* Investigation of Transcarotid CAS With Dynamic Flow Reversal in Subjects With Significant Extracranial Carotid Stenosis; *TCAR,* transcarotid artery revascularization; *TFCAS,* transfemoral carotid artery stenting.

unclamped, the arterial sheath is removed, and a purse string is tied while the venous sheath is removed and manual pressure is held. The neck incision is generally closed in multiple layers, and the patient is transferred to the ICU. Protamine administration is shown to reduce the risk of bleeding after TCAR, with no increase in MI, stroke, death, or pulmonary embolism.[78]

Postoperative Care

Patients are admitted to the ICU postoperatively. Generally, this period has a high risk of embolic stroke or hemodynamic instability. The TCAR stent can create carotid sinus simulation, leading to the need for vasopressors or inotropes. This is more likely to occur if poststent ballooning was performed. In patients who are recognized as having a TIA or stroke, a carotid duplex or CTA should be obtained.

Patients are maintained on aspirin indefinitely and clopidogrel for at least 4 to 6 weeks postoperatively. Surveillance imaging is obtained within 1 month after the procedure, at 6 months, and annually.

Perioperative Complications

Similar to TFCAS, stroke is the most concerning postoperative complication. ROADSTER II included over 600 patients between 2015 and 2019 and found a stroke rate of 1.9%; composite stroke and death rate of 2.3%; and composite stroke, death, and MI rate of 3.2%, all lower than TFCAS from CREST.[79] One-year results from ROADSTER I found a 96% stroke-free survival.[80] Additionally, a propensity-score-matched analysis found no difference in stroke/death-free survival between TCAR and CEA or TCAR and TFCAS.[81] The Society for Vascular Surgery Vascular Quality Initiative (VQI) created a TCAR Surveillance Project to track the outcomes of TCAR in order to provide data to compare with traditional CEA or TFCAS.[82] Data from this project have found a significantly decreased risk of stroke and death in TCAR compared with TFCAS and similar rates compared with CEA.[83–86] Finally, other complications include wound infections, hematoma, and access site issues.

Stroke rates after TCAR have been studied extensively and found to be 1.4% in the ROADSTER study and 1.6% in the VQI surveillance project.[74,86] CCA dissection can occur if the CCA depth is over 4 cm or if a floppy guidewire is used. Our technique described previously has been effective in avoiding dissection in our practice. A rare complication can be intolerance to flow reversal, which can be relieved with oxygen, elevated blood pressure, changing the flow to low, or ischemic preconditioning.[75] High-risk lesions for embolization include an ulcerated symptomatic lesion with thrombus.

Cerebral hyperperfusion and intracranial hemorrhage manifest as a headache and can be seen in patients who are hypertensive or have bilateral carotid artery stenosis.[87,88] Cervical hematoma can also occur, and risk can be reduced with use of protamine. Cranial nerve injury can occur with both carotid dissection and clamping.

Overall, the goal of TCAR is to provide an acceptable alternative to TFCAS in patients who are unable to undergo CEA. ROADSTER I and II have shown comparable rates of stroke and death to CEA; however, there currently are no clinical trials comparing TCAR and CEA directly (Table 101.6). Next steps for TCAR would involve high-level clinical evidence data to support the use of TCAR outside of high-risk patients. Preliminary data from the VQI found that in a propensity score matching between standard-risk patients undergoing CEA or TCAR, there was no difference in stroke, death, or MI even up to 1 year postprocedure.[89] This has led to recent expansion of TCAR for standard-risk patients as well.

In terms of cost-effectiveness, TCAR was found to be more expensive than CEA after 5 years but had higher quality-adjusted life years than CEA, and ultimately, after 6 years, TCAR was also more cost-effective.[77] Overall, once a patient is determined to meet criteria for operative intervention for carotid artery stenosis, the decision between CEA, TFCAS, and TCAR is based on patient physiologic and anatomic factors. TCAR has been introduced as a novel hybrid therapy that has outcomes similar to the gold-standard CEA.

LONG-TERM FOLLOW-UP AND COMPLICATIONS

Follow-Up

Patients who undergo carotid revascularization should be followed longitudinally to assess for long-term sequelae. It is the authors' practice to obtain an ipsilateral carotid duplex at 30 days postprocedure to ensure no early abnormalities are apparent at the endarterectomy site. A bilateral carotid duplex is then performed at 6 months, then at every 12 months thereafter. Any abnormal findings identified on duplex are then often followed with a CTA scan to better characterize the lesion.

Restenosis

Approximately 10% to 15% of patients will experience restenosis of the carotid revascularization site under long-term follow-up. This may be slightly higher for stenting than for CEA, but rates of neurologic sequelae are similar. Patients presenting with focal neurologic symptoms and restenosis should be considered for repeat revascularization, the mode of which should be complementary to the index procedure. There is persistent debate on how patients with asymptomatic restenosis should be treated, and management remains individualized.

NONATHEROSCLEROTIC CAROTID DISEASE

Fibromuscular Dysplasia

Fibromuscular dysplasia (FMD) is a nonatherosclerotic, noninflammatory disease process classically described on imaging as a string of beads. It typically affects medium-sized arteries in the media, and the majority of cases are in females. If symptomatic in the carotid artery, patients typically describe headaches, TIA, stroke, or pulsatile tinnitus.[90] The US Registry, which tracks individuals with FMD, found that almost half of these individuals will present with either aneurysms or dissections.[91]

Clinical presentation is highly variable, and FMD can even be an incidental finding. Physical examination can be significant for Horner syndrome, cranial nerve abnormalities, or bruits.[92,93] Additionally, patients are diagnosed based on carotid duplex imaging, with typical disease pattern occurring in the distal carotid artery, and sometimes additional imaging with angiography is warranted to better assess the carotid artery distal to the lesion.[94] In terms of noninvasive imaging, both CTA and MRI can be used; however, CTA has been found to be more closely correlated to angiography.

Treatment for FMD can be either medically managed or surgically managed. Medical management consists of antiplatelet therapy. Surgical management consists of dilation with angioplasty and, less likely, stent placement. When FMD is treated in the renal arteries, balloon angioplasty is performed without stent placement. There is a paucity of literature on carotid FMD treatment.

Carotid Dissection

Dissection of the carotid artery is generally uncommon but occurs when blood is able to permeate through the vessel layers through intimal tear and can lead to stenosis or occlusion in the acute setting and aneurysm in the chronic setting. Causes can be iatrogenic, traumatic, or spontaneous. Spontaneous dissection has been associated with bony structure contact of the carotid artery, chiropractic manipulation, or underlying vascular anomalies. Clinical symptoms may either mimic a headache or can present as Horner syndrome. Traumatic dissection can occur after blunt injury in approximately 1% of patients.[95]

The gold standard for diagnosis is four-vessel cerebral angiography, which allows the lesion and artery to be identified. Dissection is identified with an intimal flap or two lumens, which can also be found on ultrasound. Occlusions are described as tapered and occur proximally in the artery. Additional diagnosis modalities include ultrasound, CTA, and MRA. Filling defects, luminal irregularities, contrast extravasation, and occlusion can all be identified.

In patients who present with carotid artery dissection, up to 50% can present with ischemic stroke or TIA.[96] After blunt trauma, patients with carotid dissection can have a 25% mortality risk and a 50% risk of permanent neurologic damage.[95] The Cervical Artery Dissection in Stroke Study (CADISS) studied over 200 patients randomized to either antiplatelet agents or anticoagulants and found that individuals with dissecting aneurysms had the same risk for a stroke in both groups. The overall main treatment strategy for carotid dissection is antithrombotic therapy. For surgical management, options include either endovascular or open surgical.

In terms of overall treatment for carotid artery dissection, there are no clinical trials that compare antiplatelet therapy with anticoagulation or open surgical intervention with endovascular intervention. In general, surgical intervention is pursued in patients with a change in clinical neurologic examination or inability to tolerate or respond to medical therapy. Given the distal nature of carotid dissections, surgical exposure can be challenging. Surgical management includes ligation, saphenous vein interposition, or patch angioplasty. Endovascular management includes stenting, coiling, and embolization (Fig. 101.10).

Carotid Aneurysm

Carotid aneurysms are a rare entity that can be caused by infectious processes, pseudoaneurysms secondary to trauma, atherosclerotic degeneration, or previous carotid surgery. In terms of clinical findings, aneurysms can be identified by a painless pulsatile mass, TIA, stroke, cranial nerve dysfunction, dysphagia, or rupture.[97] They are confirmed on imaging with ultrasound, CTA, or MRA. The imaging modalities also help determine the treatment approach and accessibility of the aneurysm.

Carotid aneurysms, unlike other carotid pathologies, are treated once identified because of the high rate of TIA, stroke, or rupture.[97] Treatment involves either open surgical or endovascular therapies. Open techniques involve ligation or resection with interposition bypass reconstruction. Endovascular treatment involves covered stent placement, thrombin injection, or coil embolization. We have described the first two carotid aneurysms treated with covered stent through a TCAR approach with flow reversal. This technique minimizes the risk of embolization from the aneurysm and dramatically reduces the technical challenges of a transfemoral approach for delivering covered stents (Fig. 101.11).[98] Mycotic aneurysms are treated with antibiotic therapy followed by open surgical intervention.

DISSECTION/INTRAMURAL HEMATOMA

Classification

There are two major classification schemes for aortic dissections (AD; Fig. 102.1). The DeBakey classification was the first attempt to distinguish two clinically different scenarios—that is, dissections limited to the descending aorta versus those involving the ascending aorta. When the ascending aorta is involved, the dissection is either a type I (involving the entire ascending aorta, arch, and to some extent, descending aorta) or a type II (limited to the ascending aorta only). Dissection of the descending aorta alone is a DeBakey type III, with further subdivisions of IIIa (tear only in the descending thoracic aorta) and IIIb (tear extending below the diaphragm). The Stanford classification scheme is limited to type A, which encompasses dissections with *any* involvement of the ascending aorta, and type B, which is for dissections distal to the left subclavian artery (SCA). The original Stanford scheme thus distinguished between surgical management (type A) and medical management (type B), although there were exceptions. With the advent of endovascular therapy, there has been a shift away from medical management and toward endovascular intervention for type B dissections. The DeBakey scheme can also be separated into surgical (type I and II) and nonsurgical (type III), but in contrast to the Stanford classification, it also provides information on the extent of the disease process. More recently, there has been an interest in a modification of the Stanford scheme with a non-A, non-B subgroup. By convention, the classical separation between an acute and chronic dissection occurs at the 2-week mark, but a recent modification includes four domains: hyperacute (<24 hours), acute (2–7 days), subacute (8–30 days), and chronic (>30 days).[1] The DeBakey and Stanford classification schemes remain the most used designations clinically and in the literature.

Pathology, Management, and Outcomes

Aortic Dissection, Intramural Hematoma, and Penetrating Ulcers

We consider AD, intramural hematoma (IMH), and penetrating aortic ulcers (PAUs) together because of the interplay between these three disease states, and each may be representative of the same disease within a spectrum and, in fact, may occur together. What separates the three, in part, is the level of involvement of the aortic wall. Whereas aneurysmal disease involves all three layers of the aorta, PAU is a disease of the intima and media, and AD and IMH are diseases of the media, with significant overlap between the three.

Aortic Dissection

Acute AD is the most common clinical emergency involving the aorta, but the incidence is only an estimate for a number of reasons, including difficulties in making the diagnosis antemortem. Various prospective population studies and retrospective registries give estimates of the incidence range from 3.5 to 16.3 cases per 100,000 patient-years. Males are more frequently diagnosed with an AD compared with females (16 per 100,000 compared with 7.9 per 100,000), and females present later, are older, and have worse in-hospital and surgical mortalities. Type A ADs (TAADs) occur more commonly than type B ADs (TBADs) by 2:1; TBAD is more common than TAAD among Black patients (52.4% vs. 47.6%). Compared with aneurysmal disease, dissections occur in all age groups, although there is a bimodal pattern, with older patients having associated risk factors of hypertension and atherosclerosis and younger patients having connective tissue and genetic disorders as well as bicuspid aortic valve disease.

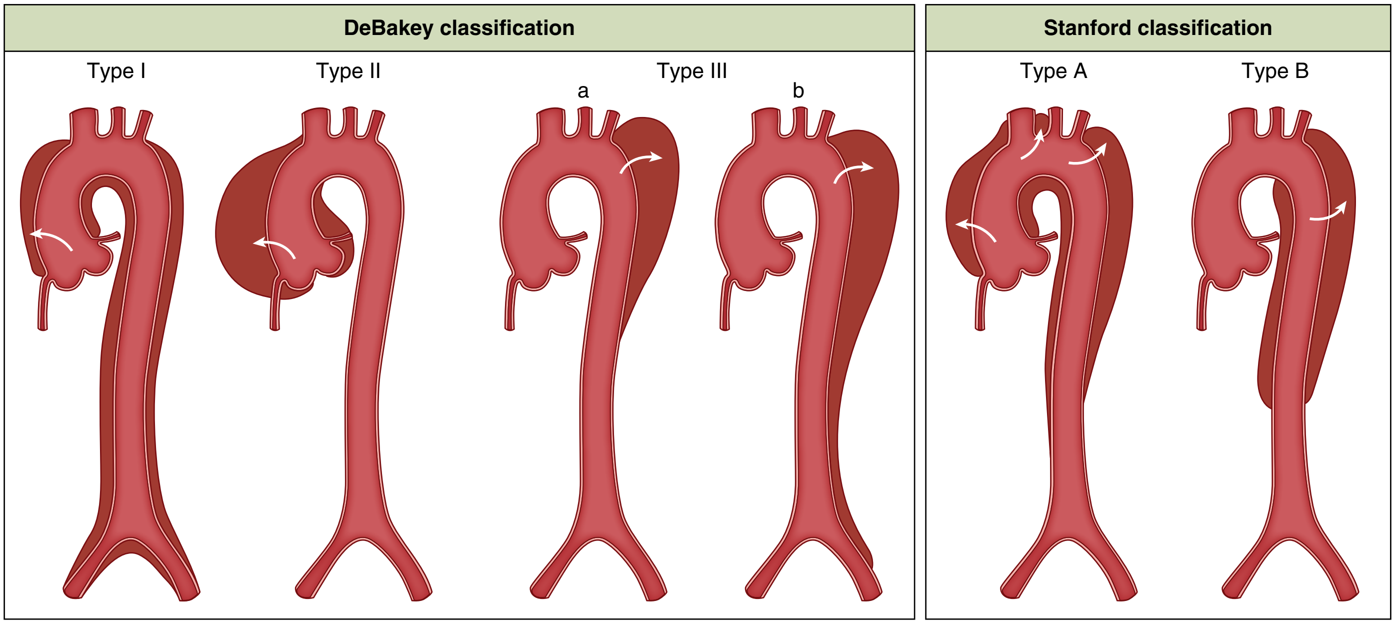

FIGURE 102.1 DeBakey *(left)* and Stanford *(right)* aortic dissection classifications.

Predisposing risk factors of hypertension, connective tissue disorders, vascular inflammation, and disruption of the intima and media (e.g., PAU and IMH) may play a role in the mechanisms leading to the initiation of an AD. Syndromes associated with AD include those with well-known genetic markers and mutations, such as Marfan syndrome (mutation of *FBN1*) and Loeys-Dietz (mutation of *TGFB1, TGFBR2,* and *TGFB*), as well as less commonly affected genes, such as *MYH11, ACTA2,* and *SMAD3.* Some of these mechanisms may also play a role in the development of aneurysmal disease and IMHs. When illicit drug use, including cocaine and methamphetamines, is present or suspected, patients tend to be younger and have type B dissections. It may not be the acute use of cocaine and associated hypertension but rather the long-term atherogenic effects of cocaine that predispose to AD. Finally, there are potential environmental and social factors that may transcend genetic factors alone. The Registry of Aortic Dissection in China (Sino-RAD), in comparison to the International Registry of Acute Aortic Dissection (IRAD), describes acute TAADs in the Chinese population to occur at an earlier age (mean age 50.5 vs. 61.1 years), with less hypertension (51.4% vs. 67%) and greater predominance of males (76.3% vs. 66.9%).

AD can mimic a variety of other medical problems, including acute coronary syndrome, stroke, paraplegia, lower extremity ischemia, acute renal failure, and an abdominal catastrophe, with each of these problems being attributable to malperfusion. In a review of 526 patients who ultimately had the diagnosis of an acute TAAD, although 90% of these patients had pain as a presenting symptom, in slightly over 20%, the pain was localized in the abdomen.[2] In the same study, the so-called pathognomonic sign of absent or differential pulses was present in only 139 of the 526 patients, and only 31% of patients had normal electrocardiograms (ECGs), with more than 25% of patients having ECG findings of myocardial ischemia, infarction, new Q waves, or ST-segment deviations. Such ECG findings could lead to the misdiagnosis of an acute coronary syndrome. Putting the difficulty in diagnosis in perspective, the incidence of AD is up to 16 per 100,000, which is lower in comparison to acute coronary syndromes (440 per 100,000) and pulmonary embolism (69 per 100,000), both of which can present similarly to AD.

Before the widespread introduction and implementation of computed tomography (CT), the diagnosis of an AD was made at autopsy in >25% of patients with the disease. Both CT and magnetic resonance imaging (MRI) are useful in the diagnostic confirmation of a dissection, with sensitivities and specificities reported to be as high as 100%. CT imaging has the added benefit of providing the “triple rule-out”—that is, specific protocols regarding the timing of contrast to rule out (or rule in) dissection, pulmonary embolism, or coronary artery calcification. Transthoracic echocardiography (TTE) is of limited utility for TAAD and has no utility in type B. For TAAD, TTE has a sensitivity range of 35% to 80% and a specificity range of 35% to 96%, depending on the location of the tear, and a normal TTE cannot exclude the possibility of a dissection. Transesophageal echocardiography (TEE) is more specific (63%–96%) and sensitive (98%) in diagnosing TAAD and will detect a flap in the descending thoracic aorta as well. Shiga et al. demonstrated that pooled sensitivities (98%–100%) and specificities (95%–98%) were comparable between TEE, contrast CT, and MRI.

TAADs are surgical emergencies requiring, with rare exceptions, open surgical repair. Current guideline recommendations include surgical management for TAADs, with the caveat that stable patients can potentially be transferred to centers with expertise. Medical management with impulse control therapy can be used either as a temporizing measure or for palliation in patients not deemed to be surgical candidates, but although surgical outcomes have improved with time, medical-management mortality remains unchanged.[3]

A frequently quoted risk of mortality is 1% to 2% per hour in the first 24 hours. Although this is likely true for untreated TAAD, medical management with blood pressure and antiimpulse therapy will reduce the 24-hour mortality rate. Subsequently, with surgical intervention, hospital and operative mortality becomes more of a function of patient characteristics than time to diagnosis and treatment. Large clinical databases (such as IRAD) provide fodder for univariate and multivariate analyses and subsequent development of risk models. Mehta et al. identified age ≥70 years, abrupt onset of chest pain, shock/tamponade, kidney failure, pulse deficit, and abnormal ECG to be factors in postoperative mortality. A subsequent refinement divided the model into preoperative factors as well as intraoperative findings, with the need for coronary artery bypass grafting (CABG) and/or right ventricular dysfunction boding poorly. Interestingly, right hemiarch replacement was a favorable factor, and open hemiarch repair is included in recent guideline recommendations.[3] A recent observation that patients without evidence of malperfusion had a lower mortality rate than those who presented with malperfusion has led to the development of a risk score that considers three variables: creatinine, lactic acid, and evidence of liver malperfusion.[4] The gamut of symptoms described by Elefteriades et al.[5] is primarily due to different degrees and distributions of malperfusion, raising the issue of whether to address the malperfusion before surgical repair of the dissection. This appears to have some benefit for operative mortality but may increase the risk for early and late mortality, and the challenge is to develop an algorithm to identity patients who will benefit from revascularization before central repair. Overall operative mortality rates for acute TAAD are typically reported in the range of 15% to 25% and are in single digits in specialized, multidisciplinary aortic surgery programs.[6]

Surgical Management of Acute Type A Aortic Dissection

Open surgical repair of an acute TAAD remains the standard of care when the patient is a surgical candidate. As reported by IRAD, in tertiary medical centers with expertise in the treatment of acute TAAD in the years from 1995 to 2013, the proportion of patients relegated to medical management declined from 21% to 10%, with a corresponding decline in surgical mortality rate from 25% to 18%.[7] Relative contraindications to surgery include advanced age, multiple comorbidities, and neurologic status. Stamou et al. did not see a difference in operative mortality or major morbidity in a comparison between patients ≥70 years and those younger,[8] but octogenarians do not fare as well. IRAD data have shown no difference in outcomes for octogenarians treated with surgical versus medical intervention. The presence of cerebrovascular accident (CVA) or coma has a significant impact on hospital survival, but for patients who undergo surgical repair, there is improved survival compared with medical management, and it remains a recommended strategy.[3] In 84.3% of patients presenting with CVA who underwent surgical repair, there was resolution of the neurologic deficit.

Once the decision is made to proceed with surgery, the primary goal of surgery is the elimination of the entry tear and obliteration of the false lumen in the aortic root and ascending aorta. Successful completion of these goals will often address secondary issues such as aortic valve insufficiency and distal visceral malperfusion. Specific considerations are the cannulation strategy, cerebral protection, conduct of cardiopulmonary bypass (CPB), and the proximal and distal extent of resection and repair.

Traditionally, femoral cannulation was the primary access for establishing arterial inflow for CPB, in part because of the ability to rapidly establish access via either surgical cut-down or percutaneously. The decision as to which vessel to approach is paradoxical in the sense that the femoral artery most likely to be in continuity with the true lumen is the one without the pulse (due to true lumen collapse). The clinical situation where true lumen collapse was occurring and the wrong vessel was cannulated would result in high circuit line pressures. Malperfusion from femoral cannulation is uncommon. Axillary artery access grew popular in part because of the ability to use this approach as part of a selective cerebral perfusion technique during periods of circulatory arrest as well as avoidance of atheroembolization and false lumen perfusion.[3] Other approaches include arterial access via the apex of the left ventricle with the cannula traversing the aortic valve, direct cannulation of the true lumen after transection of the ascending aorta, and echo-guided cannulation of ascending aorta/arch using a Seldinger technique.

TABLE 102.1 Level of Hypothermia and Duration of Circulatory Arrest

LEVEL	NASOPHARYNGEAL TEMPERATURE (°C)	ESTIMATED SAFE DURATION OF CIRCULATORY ARREST (MIN)
Mild hypothermia	28.1–34	<10
Moderate hypothermia	20.1–28	10–20
Deep hypothermia	14.1–20	20–30
Profound hypothermia	≤14	30–40

Adapted from Yan TD, Bannon PG, Bavaria J, et al. Consensus on hypothermia in aortic arch surgery. *Ann Cardiothorac Surg.* 2013;2:163-168.

With some exceptions, acute TAAD repair is performed with a period of hypothermic circulatory arrest. The initial approach to the arch reported by DeBakey et al. included a multicatheter approach to the great vessels and one of the femoral arteries to provide arterial inflow without circulatory arrest. Hypothermic circulatory arrest (Table 102.1) allows the establishment of a bloodless field, allowing for the evaluation of the distal ascending aorta and arch to confirm intimal integrity; ensures graft continuity to the true lumen; and assists in obliteration of the false lumen. Profound hypothermic circulatory arrest provides 30 to 40 minutes of protective cerebral time; deep hypothermia alone should be sufficient for open-distal and hemiarch repairs. The use of unilateral selective antegrade cerebral perfusion (SACP) or bilateral antegrade cerebral circulatory perfusion extends this protective time. With the adjunct of SACP, moderate hypothermia has been shown to be safe and effective. Cerebral perfusion during SACP (with right axillary cannulation) is via the right carotid and assumes the absence of right carotid stenosis and an intact circle of Willis. Concern for coagulopathy secondary to hypothermia has been raised, but adequate rewarming should be sufficient to address this concern.

Once the patient is successfully cannulated and CPB initiated, systemic cooling is started with the target temperature based on surgeon preference, experience, and patient characteristics. Topical ice on the patient's head is typically included, although evidence of its efficacy is limited. There is currently no consensus regarding the rate of cooling or the acid-based management strategy (alpha stat versus pH stat) during cooling, and the surgeon should discuss the target temperature with the anesthesia and perfusion team as part of the operative plan. Routine clamping of the ascending aorta during cooling is not necessary. Distention of the left ventricle may occur because of the presence of aortic valve insufficiency. If the distention is significant, the ventricle can be vented in several ways, including catheters inserted via the right superior pulmonary vein, the pulmonary artery, or directly via the apex of the ventricle. If unsuccessful in reducing the distention, the ascending aorta can be clamped and transected proximally with concomitant myocardial protection via retrograde or direct antegrade cardioplegia. When the distal anastomosis is completed first, the anastomosis can be tested with direct vision of the entire suture line, and rewarming is then initiated while the proximal aorta is dealt with.

If selective cerebral perfusion and circulatory arrest is used, when the target temperature is achieved, the patient is placed in a Trendelenburg position, and the surgical field can be flooded with CO_2 to minimize cerebral microbubbles when the arch is opened. The ascending aorta is then opened, and the arch is examined. Once the extent of repair has been decided, the base of the innominate artery is clamped, and SACP is started with a typical rate of 10 to 15 cc/kg and perfusion pressure of 40 to 50 mm Hg. The extent of repair, both proximally and distally, has also been a subject of debate. The aortic root is not infrequently involved, and resuspension of the aortic valve commissures in addition to reapproximating the walls of the sinuses is often sufficient to provide integrity to the aorta and correct aortic valve insufficiency. Barring this, the root should be addressed at the time of repair.

Management of Type B Dissection

Medical management of type B dissections is favored initially unless there is evidence of rupture or malperfusion (complicated TBAD). Selective β-blockade remains the preferred first-line treatment and has the dual ability to lower blood pressure and reduce aortic tension from the pressure impulse (dP/dt). The goal is a reduction of pulse pressure while maintaining end-organ perfusion, with an appreciation that some antihypertensive medications may increase pulse pressure while reducing mean arterial pressure secondary to their preferential impact on lowering diastolic pressure. With the development of endovascular techniques, thoracic endovascular aortic repair (TEVAR) has emerged as the treatment of choice for complicated TBAD (i.e., with rupture or malperfusion) and as an option for noncomplicated dissections with high-risk features.[3] Medical management remains the recommended standard of care for acute and chronic noncomplicated TBAD.[3] The primary goals of endovascular therapy include coverage of the primary intimal tear and obliteration and/or thrombosis of the false lumen. Fattori et al. showed that in-hospital mortality for open surgical repair of acute TBAD was almost 34%, whereas TEVAR and medical management were both in the range of 10%.[9] Most patients (68.3%) in this study were medically managed with open surgical repair, with TEVAR reserved for complicated dissections; the mortality rate for open surgically managed patients seen was substantially higher than in other studies, as noted in a subsequent meta-analysis, where the pooled mortality rate was 17.5%. The disparity in results may reflect the paucity of studies that directly and randomly compare TEVAR with open surgery or medical management as well as clear distinctions between complicated versus uncomplicated designations and acuity.

The first prospective trial to investigate TEVAR for uncomplicated acute TBAD was the INSTEAD (Investigation of Stent Grafts in Aortic Dissection) trial.[10] At 2 years, there was no difference in all-cause or aortic-related deaths, but remodeling was favorable in the TEVAR group compared with the medical-management cohort.[11] These results were attributed to an underpowered study. The ADSORB (Acute Dissection: Stent Graft OR Best Medical Therapy)[12] trial was a small trial prospectively comparing best medical therapy (BMT; $n = 31$) with BMT and TEVAR ($n = 30$) in patients with uncomplicated TBAD. The end point was a composite of completeness of false lumen thrombosis, continued aortic growth ≥5 mm or a maximum aortic diameter ≥55 mm, or descending or abdominal aortic rupture at 1 year. At 1 year, the results favored BMT and TEVAR, chiefly because of completeness of false lumen thrombosis in the BMT and TEVAR group (57% vs. 3%, $p < 0.001$). The clinical significance of the findings from ADSORB, which was not powered to detect differences in aortic-related and all-cause mortality, remains unclear. An extension of the INSTEAD trial (INSTEAD-XL) did find a benefit in aortic-related mortality in the TEVAR cohort at 5 years.[13]

The provisional extension to induce complete attachment (PETTICOAT) technique was initially described as an adjunct to TEVAR for complicated acute type B dissection.[14] The original report noted that in 12 of 100 patients treated with TEVAR, there was persistent flow in the distal false lumen with true lumen collapse. With the subsequent deployment of an uncovered stent distal to the previously implanted stent graft, there was reperfusion of the true lumen and abolishment of malperfusion. These results persisted at 1 year, and there was evidence of improved aortic remodeling. This technique has been modified further to address the distal aorta in open repair of acute TAAD (DeBakey type I) as part of a frozen elephant trunk technique. An "extended" technique (e-PETTICOAT) has been proposed to preemptively address the entire descending thoracic and abdominal aorta, with the anticipated benefits being complete aortic remodeling and prevention of aneurysmal progression. The IMPROVE-AD (Improving Outcomes in Vascular Disease–Aortic Dissection) study will hopefully shed light on the optimal approach to TBAD and endovascular surgery.

Intramural Hematoma

IMH is a subadventitial lesion usually involving the outer third of the media. The nomenclature of IMH follows the Stanford dissection classification, so IMH involving the ascending aorta is type A IMH, and that confined to the descending aorta is type B IMH. One common hypothesis for the development of IMH is the rupture of a vaso-vasorum with subsequent intramural bleeding and hematoma formation, but others have suggested that IMH may reflect an unrecognized AD subsequently seen on pathologic examination or demonstrated using submillimeter-spatial-resolution contrast-enhanced multidetector CT.

IMH accounts for approximately 10% of acute aortic syndromes (AASs) in Western countries, and the rate may be higher in Asian countries. The incidence may be underestimated due to either misclassification of IMH as a discrete dissection or the evolution of IMH into an AD during transfer to a tertiary center for treatment. In contrast to AD, there is a slight predominance of IMH seen in females compared with males, type B IMH occurs more frequently than type A IMH, and patients with IMH tend to be older and more likely hypertensive.[15] Marfan syndrome or other connective tissue disorders do not appear to play a role in the development of IMH. Like AD and PAU, patients present with chest or back pain, but in contrast, the pain in IMH does not often radiate. In contrast to TAAD, with type A IMH, aortic valve insufficiency, distal malperfusion, and ECG abnormalities are not as frequent, but the presence of a pericardial effusion is increased in incidence.

The *sine qua non* for diagnostic noninvasive imaging requires the presence of a thickened aortic wall (localized or circumferential)

>5 mm with no detectable blood flow on CT imaging, and the combination of CT imaging with and without contrast has reported sensitivities of >95%.[16] TEE has been shown to have both a high sensitivity (100%) and specificity (91%) for IMH.

Management of IMH is similar to that of AD, with medical management generally limited to type B IMH, with a selective β-blocker as the therapy of choice. Medical-management failure includes persistent pain, uncontrollable hypertension, progressively enlarging wall thickness >11 mm, and recurrent pleural effusions.[16] Interestingly, in contrast to AD, Falconi et al. demonstrated that medical and surgical management of type B IMH had similar mortality rates (19% vs. 17%, respectively),[17] and because of this, type B IMH is more likely to be managed medically than TBAD.

Emergent or urgent management of type A IMH is typically recommended, especially in the setting of a pericardial effusion and ongoing pain, although in a selected group of patients, initial medical management and optimization have been reported. Open surgical repair of type A IMH proceeds similar to that of TAAD, with two caveats. First, "normal" aorta may not be identified distally, so surgical judgment as to the extent of resection is important, and second, clamping of the aorta may convert the IMH into a dissection upon release of the cross clamp, presumably because of the creation of intimal tears with the placement of the clamp.

Like TBAD, endovascular repairs have emerged as a treatment option for type B IMH. For an uncomplicated type B IMH, the European Consensus Guidelines recommend initial medical management and surveillance with noninvasive imaging (class I recommendation). With expansion of the hematoma, development of a periaortic hematoma, recurrent pain, or conversion to a frank dissection, TEVAR (class IIa) or open repair (class IIb) is recommended.[16] Bischoff et al. compared TEVAR with medical management and, in support of the equipoise seen by Falconi et al., found no difference in early or late mortality, incidence of complete remodeling, or regression between the two groups.[18] The results suggest that TEVAR might be reserved for specific cases of type B IMH. The difficulty with TEVAR in type B IMH is determining the extent of coverage, similar to determining the extent of open repair. Because there (by definition) is no primary intimal tear, coverage territory becomes either presumptive of where the process started or targeted in the case of a periaortic hematoma or associated PAU.

Penetrating Aortic Ulcer

PAU involves both the intima and media, arising from an ulceration of an atherosclerotic plaque that has penetrated the elastic lamina. PAU can be associated with IMH, serve as a nidus for AD, or lead to the development of a saccular pseudoaneurysm. Coady et al. found that 7.6% of their patients treated for either TAAD or TBAD had an associated PAU.[19] Isolated PAU accounts for 2% to 7% of AAS, and although there is an overall slight predominance in males,[19] PAU occurs more frequently in the thoracic aorta in females and more frequently in the abdominal aorta in males. When considering only the thoracic aorta in PAU, for both males and females, the descending aorta is the predominant site of occurrence 90% of the time.

In contrast to AD and IMH, pain may not be a component of PAU, and often the ulcer is detected incidentally. In a Mayo Center study, 87% of patients with PAU were asymptomatic at the time of diagnosis.[20] PAU is defined by a distinct, focal outpouching through an area of intimal calcification or in an area with associated diffuse atherosclerosis when contrast-enhanced CT scanning is performed.

Asymptomatic PAU may be managed medically with antiimpulse therapy and routine surveillance noninvasive imaging, but early intervention has been suggested for large PAUs, specifically when the greatest diameter is >20 mm or the neck is >10 mm.[3] With open surgical repair, the involved segment is resected and replaced with a prosthetic graft or homograft. Because PAU is associated with, and defined by the presence of, severe atherosclerosis and calcification, finding normal aorta proximally and/or distally to sew to may be difficult. Although studies on the efficacy of endovascular repair for PAU are lacking, limited data have shown good results for TEVAR in the setting of PAU and pseudoaneurysm formation or rupture. The same challenge for open repair of PAU, namely, extensive atherosclerosis, may pose problems if the atherosclerotic disease extends into the peripheral (and therefore access) vessels or if the presence of laminated thrombus associated with PAU makes achieving a safe landing zone difficult.

AORTIC ANEURYSM

Pathophysiology

Aneurysms, typically defined as an increase in size of more than 50% above the normal arterial diameter, may occur anywhere along the aorta, from the aortic root to the bifurcation. Because the mean aortic diameter differs between the ascending, descending, and infrarenal aorta, the absolute size criteria for aneurysm changes. Normal values will also vary due to methods of measurement, the patient's age and sex, and other factors. Anatomy or etiology may also be the basis for characterization of aneurysms. Anatomically, fusiform aneurysms exhibit smooth, circumferential dilatation across the entire vessel, as opposed to saccular aneurysms, which appear as a focal outpouching of the arterial wall. Whereas true aneurysms involve all three layers of the vessel wall, *false aneurysm* or *pseudoaneurysm* describes a focal defect in the artery with an associated collection of blood contained by surrounding connective tissue. Pseudoaneurysms may be degenerative, infectious, or traumatic in etiology. These pseudoaneurysms may occur at sites of prior surgical anastomosis and represent anastomotic disruption. The majority of aneurysms addressed in this chapter are degenerative in nature. Less frequently, aneurysms may be associated with infection, inflammation, or autoimmune or connective tissue disease. These cases merit special consideration in their evaluation and management.

Aneurysmal enlargement of the aorta is associated with factors that result in weakening of the arterial wall and increased local hemodynamic forces. These may include heritable conditions, such as Marfan syndrome, familial thoracic aortic aneurysm and dissection, and vascular-type Ehlers-Danlos as well as less well-defined entities that contribute to the significantly elevated incidence of aneurysm in patients with a family history of aneurysm. Factors that contribute to the degradation of extracellular matrix and reduction of elastin concentration are also associated with aneurysmal disease, and research in this area has focused on the role of matrix metalloproteinases, both their presence in the aneurysm specimens and for deficits of antiproteolytic enzymes that normally inhibit metalloproteinases. Ongoing avenues of investigation in this area also include the role of the immune response and hormone milieu. Finally, aneurysmal dilatation may also occur as a degenerative complication after AD.

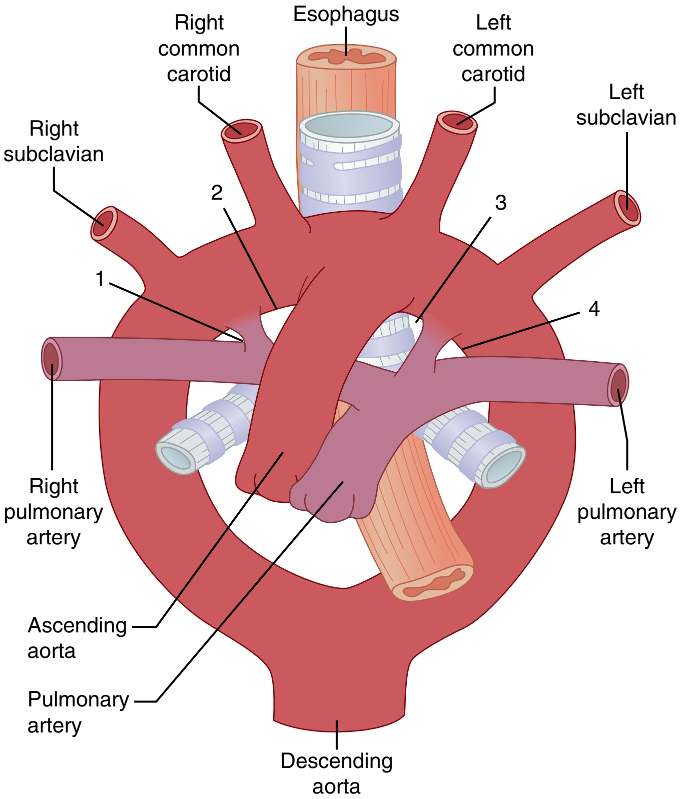

FIGURE 102.2 Edwards theoretical arch.

Clinical Presentation

Aortic pathologic conditions have their own unique nomenclature. Aneurysmal disease is perhaps the easiest to describe because typically, the label is simply the location (e.g., root aneurysm, arch aneurysm), with some exceptions. For example, Estrera and colleagues subdivide the descending thoracic aorta into three subtypes (A: proximal to the sixth rib, B: distal to the sixth rib, C: entire descending thoracic aorta) because this has implications for the risk of postoperative paraplegia (Fig. 102.2).[21] The Society for Vascular Surgery (SVS) divides the aorta into "zones," which pertain to endograft attachment sites rather than to disease extent (Fig. 102.3).[22] In the case of thoracoabdominal aortic aneurysms (TAAAs), first catalogued and subsequently refined by Crawford and colleagues, the original groupings attempted to describe the aneurysm in relationship to the extent of thoracic and abdominal involvement. The label "group" later evolved into "extent" or "type." Extent I involved the descending thoracic aorta and abdominal aorta to the level of the celiac artery. Extent II involved the entire thoracic and abdominal aorta, and extent III had lesser involvement of the thoracic aorta and most of the abdominal aorta. Extent IV involved the entire abdominal aorta. In the original classification scheme, there was also an extent V, which involved the lower abdominal aorta and renal arteries. This classification scheme was refined to four groups, or extents, and later modified to five extents to account for aneurysms involving only a portion of the thoracic aorta with sparing of the infrarenal aorta (Fig. 102.4). The Crawford classification system remains as an important tool in comparing procedural outcomes for TAAAs.

Determining the incidence and prevalence of aneurysmal disease is difficult, in part because of the tendency for aneurysms to be asymptomatic and found incidentally during imaging for unrelated medical issues. The incidence of abdominal aortic aneurysm (AAA), based on large screening studies, is estimated to range from 3% to 10%. Numerous risk factors, in addition to genetic or familial disorders, for the development, expansion, and rupture of AAAs have been identified (Table 102.2). Risk factors for development of an AAA include age, male sex, concurrent aneurysms, family history, tobacco use, hypertension, hyperlipidemia, and height. Female sex, Black race, and diabetes appear to be protective.[23] Recent studies have suggested that in first-world countries, the incidence has been decreasing over the past two decades, most likely related to the decreased tobacco burden in those countries. Sex differences extend to the presentation, associations, and natural history of aneurysms. Males with AAA, for instance, are more likely to present with concurrent iliac or femoropopliteal aneurysms. Females are more likely to experience rupture and consistently demonstrate poorer outcomes after repair, perhaps because of a significantly higher incidence of challenging anatomy. With screening of an at-risk population, specifically for the 65- to 89-year-old demographic, the incidence of AAA is 5% to 7%, with a male-to-female ratio of roughly 4:1. Estimates of the prevalence of thoracic aortic aneurysms are 400 per 100,000 patients in 65-year-olds and 670 per 100,000 in 80-year-olds, and in contrast to AAA, there does not appear to be a sex difference.

Although aneurysms may be asymptomatic, an acutely enlarging or inflamed aorta may present with pain. Depending on the

TABLE 102.2 Risk Factors for Aneurysm Development, Expansion, and Rupture

SYMPTOM	RISK FACTORS
AAA development	Tobacco use
	Hypercholesterolemia
	Hypertension
	Male sex
	Family history (male predominance)
AAA expansion	Advanced age
	Severe cardiac disease
	Previous stroke
	Tobacco use
	Cardiac or renal transplantation
AAA rupture	Female sex
	↓ FEV_1
	Larger initial abdominal aortic diameter
	Higher mean blood pressure
	Current tobacco use (length of time smoking ≫ amount)
	Cardiac or renal transplantation
	Critical wall stress–wall strength relationship

AAA, Abdominal aortic aneurysm; *FEV_1,* forced expiratory volume in 1 second.

location of the aneurysm, other less common signs or symptoms may occur. For example, an enlarged ascending aorta or proximal arch may result in superior vena cava syndrome. An expanding proximal descending aorta can impinge on the left recurrent laryngeal nerve, leading to hoarseness (Ortner syndrome) or pulmonary embarrassment from extrinsic compression of the left main stem bronchus. Large AAAs may give a feeling of fullness or early satiety after small meals.

Diagnosis and Evaluation

Imaging of aortic disease is necessary to define its exact anatomic location, extent, and size. A number of imaging modalities can be used, with each having its own specific limitations and benefits. Chest x-ray (CXR) studies may detect incidental thoracic aneurysms due to abnormalities in aortic contour, size, or calcifications, but CXR is not a good screening tool. Ultrasound is an important tool in AAA management because it is accurate, noninvasive, and cost-effective. Contrast-enhanced ultrasound may be particularly useful in detecting, localizing, and quantifying endoleaks in patients after endovascular aneurysm repair (EVAR). Echocardiography is ultrasonography when performed on the chest and its contents, and the noninvasive technique is TTE. TTE is useful for measuring certain segments of the ascending aorta and assessing the degree of aortic valve insufficiency, if present. TEE, although more invasive, is useful for visualizing the thoracic aorta from the aortic annulus to the celiac axis, with the exception of a short segment of the ascending aorta proximal to the innominate artery. Intravascular ultrasound (IVUS) is an additional modality for imaging of the aorta, and although it is not typically used for diagnostic purposes, it is invaluable as an adjunct in endovascular procedures, particularly in the treatment of AD.

CT provides excellent imaging of the aorta and remains an important tool in the diagnosis, management, and surveillance of aortic disease. CT, particularly with the adjunctive use of iodinated contrast agents to perform CT angiography (CTA), provides a wealth of anatomic information; it detects vessel calcification, thrombus, and concurrent arterial occlusive disease and permits multiplanar and three-dimensional reconstruction and analysis for operative planning. Drawbacks include substantial radiation exposure, particularly in the setting of serial examinations, and the use of iodinated contrast media in a population with a high incidence of comorbid kidney disease.

MRI provides a reasonable alternative to CT for imaging of the aorta, with the benefits being the elimination of ionizing radiation and iodinated contrast. Spin-echo black blood and gradient echo sequences provide an intrinsic contrast between the blood flow and aortic wall to provide dimensional and geometric information. With the addition of intravenous gadolinium as a contrast agent, magnetic resonance angiography (MRA) provides rapid three-dimensional (3D) imaging of the aorta without the need for ECG gating. The ability to acquire dynamic images throughout the cardiac cycle allows physiologic parameters, such as estimates of wall shear stress, to be determined, which may lead to clinical applications. Unlike CT, MRI does not demonstrate aortic wall calcification, which may be important in operative planning, especially for endovascular approaches. MRI does not necessarily use iodinated contrast material but instead can use gadolinium, which has been associated with the development of nephrogenic systemic fibrosis in patients with low glomerular filtration rate. Additionally, a contraindication for MRI is the presence of incompatible metallic implants or foreign bodies. Mechanical valves, pacemakers, and implantable cardioversion devices currently marketed in the United States are MRI compatible. Newer ferrous-based contrast agents coupled with MRA may provide a viable alternative to vascular imaging when iodinated contrast or gadolinium is contraindicated.

Medical Management and Screening

Size and symptoms play a large role in determining the management of aortic aneurysms (Table 102.3). For aneurysms that do not meet criteria or appropriateness for surgical intervention, medical management is a mainstay. Lifestyle modifications may be necessary, such as tobacco use cessation. Current smoking has been associated with significantly increasing the expansion rate of AAA ($\sim$0.4 mm/yr). Although moderate levels of exercise have a beneficial impact on patient cardiopulmonary health and progression of atherosclerosis, patients should avoid vigorous levels of activity and contact sports. Activities that cause a sudden spike in blood pressure may lead to aortic rupture or dissection in the presence of underlying aortic pathology. Blood pressure management, in the reduction of both systolic pressure and pulse pressure (an indirect measure of dP/dt and wall stress), may require multiple medications. β-blockers, both selective and nonselective, are useful in accomplishing both goals.

TABLE 102.3 Recommended Size for Intervention of Asymptomatic Aortic Aneurysm

LOCATION	SIZE CRITERIA	COMMENT
Ascending/root	≥55 mm	All patients, including BAV
	≥50 mm	Patients with Marfan syndrome BAV with risk factors for dissection
	≥45 mm	Selected patients with Marfan syndrome
	>45 mm	When aortic valve is being intervened on
	>27.5 mm/m^2	For patients with a small body size
Arch	≥55 mm	All patients
	Any size	Signs or symptoms of local compression
Descending	≥55 mm	When TEVAR possible
	≥60 mm	Open repair (less for Marfan syndrome)
Abdominal	≥55 mm	All patients

Adapted from Erbel R, Aboyans V, Boileau C, et al. 2014 ESC guidelines on the diagnosis and treatment of aortic diseases: document covering acute and chronic aortic diseases of the thoracic and abdominal aorta of the adult. The Task Force for the Diagnosis and Treatment of Aortic Diseases of the European Society of Cardiology (ESC). *Eur Heart J*. 2014;35:2873-2926.

Prevention of aneurysmal dilatation or even regression would be an ideal consequence of medical therapy.[3] This has been shown to be the case in the specific clinical scenario of the patient with Marfan syndrome treated with β-blockers, angiotensin II receptor blockers, and angiotensin-converting enzyme inhibitors. None of these drugs has been shown to be effective in patients who do not have Marfan syndrome. HMG–coenzyme A reductase inhibitor (statin) therapy has been associated with reduced rates of AAA enlargement and is otherwise appropriate in a population with a high prevalence of concurrent atherosclerotic disease. Statin therapy improves survival after open and endovascular repair of AAAs and has been shown to decrease the incidence of major cardiovascular events (stroke, myocardial infarction, and death) for patients with the diagnosis of AAA. Finally, antiplatelet therapy using aspirin offers a secondary preventive benefit in this population.

Screening recommendations for aneurysms are informed by the sensitivity and specificity of ultrasound screening (or other imaging modality), the detection yield of screening based on various risk factor selection criteria, and cost. Screening for thoracic aneurysms is generally not done without a pretest high probability (e.g., suspicion of an aortic syndrome). The caveat is that when an AAA is diagnosed, it is a general recommendation that the thoracic aorta should be screened to rule out metasynchronous disease. Current consensus guidelines recommend one-time screening of all males aged 65 years and older or males 55 years and older with a family history of AAA. In 2014, the US Preventive Services Task Force (USPSTF) issued a more limited recommendation for one-time screening for AAA using ultrasonography of males between 65 and 75 years of age who have a personal smoking history and selective screening for nonsmokers. For females, the recommendations remain controversial. The USPSTF concluded that there was insufficient evidence to recommend routine screening in females who smoke and recommended against routine screening in nonsmoking females. One issue that may have biased these results is the paucity of females in large screening trials. In one meta-analysis that looked at a combination of four studies with over 125,000 patients enrolled, less than 10,000 subjects were females.[24] Payer policies regarding reimbursement may not track either of these recommendations. Medicare, for instance, because of the Screening Abdominal Aortic Aneurysms Very Efficiently (SAAAVE) Act, reflects an intermediate approach in offering a screening benefit for males with a personal smoking history and males or females with a family history of AAA, although only as a part of the initial Welcome to Medicare physical examination.

After the initial detection of a nonsurgical aneurysm, surveillance is necessary in addition to optimal medical management. Ideally, surveillance should be low cost, have high sensitivity, and pose minimal harm to the patient. For the abdominal aorta, ultrasound follow-up is advisable. Those patients with a known AAA who do not have appropriate surveillance may have up to a sixfold increase in rate of rupture. The SVS Clinical Practice Council recommends the following screening intervals based on aneurysm size (maximum external aortic diameter) and associated risk of rupture:

- <2.6 cm: no further screening recommended
- 2.6 to 2.9 cm: reexamination at 5 years
- 3 to 3.4 cm: reexamination at 3 years
- 3.5 to 4.4 cm: reexamination at 12 months
- 4.5 to 5.4 cm: reexamination at 6 months

These recommendations, as is the case for thoracic aortic aneurysms, stem from our understanding of growth rates of normal and abnormal aortas as well as published rates of rupture at given sizes. No large, prospective studies that compare surveillance intervals exist. For the abdominal aorta, although the SVS recommends no further screening for aneurysms less than 2.6 cm, others have suggested 3 cm as the cutoff. Countering this are the findings that a significant proportion of 65-year-old males (13.8%) with an initial aortic diameter of 2.6 to 2.9 cm developed aneurysms exceeding 5.5 cm at 10 years. Given current life expectancy projections, it is evident that a subset of patients deemed "normal" at screening will go on to develop clinically significant aneurysms.

With the exception of the aortic root, visible with TTE, the thoracic aorta generally requires CT or MRI contrast imaging. For the ascending aorta, arch, and descending aorta, after the initial diagnosis, a second study at 6 months should suffice to determine if there is measurable growth in the aortic diameter. This is followed with yearly scans until there is reasonable certainty of stability in size, at which time extending surveillance to a 2- to 3-year interval is tolerable. Conversion to MRI for surveillance avoids exposure of the patient to ionizing radiation.

Prevention of rupture of the growing aorta is the rationale for surveillance imaging, and risk models for rupture do exist. Juvonen and colleagues[25] developed a model that included risk factors of age, presence of pain, chronic obstructive pulmonary disease, and maximal diameters of the thoracic and abdominal aorta. Based on this model, surgery was recommended when the calculated risk of rupture within 1 year exceeded the anticipated mortality risk of an elective procedure, even if the recommended aortic diameter for intervention was not reached.

Operative Management

When the risk of continued observation exceeds the risk of operative repair, surgery is warranted. There are two main approaches to surgical repair: conventional (or open) surgery and endovascular surgery. Hybrid repair, which calls on the strengths of both open and endovascular repair in order to obtain a durable result, is also frequently a viable approach. Endovascular repair offers a less invasive approach but has limitations based on anatomic location.

Open Surgical Aortic Repair

Aortic root replacement. Aortic root replacement is primarily for aneurysmal disease or TAAD but is also performed in certain cases of aortic valve endocarditis as well as reoperative aortic valve replacement. There are three standard approaches to replacement of the aortic root: composite valve grafts (CVGs; mechanical or biologic), complete tissue replacement (either cadaveric homograft or autograft [Ross procedure]), and valve-sparing root replacement (remodeling, reattachment, and Florida sleeve).

As noted earlier, the boundaries of the aortic root are the aortic annulus proximally and the sinotubular junction distally; components of the root include the aortic valve and ostia of the coronary arteries. Thus, when the aortic root is repaired or replaced, with few specific exceptions, the coronaries are always reimplanted or bypassed, the valve is addressed (replaced or spared), and circulatory arrest is not needed unless the ascending aorta is also affected and needs to be replaced.

Modifications to the procedure, as originally described by Bentall and colleagues,[26] have made the term *Bentall procedure* an anachronism. The original description was a CVG with an inclusion technique to deal with the coronaries (i.e., sewing the coronaries onto the graft not as Carrel buttons but rather in a side-to-side fashion). Wheat preceded Bentall in an earlier publication describing a technique where the valve and graft were separate, and the coronaries were reimplanted on "tongues of aortic wall" extending from the annulus. Subsequent work by Kouchoukos and colleagues incorporated the now-familiar coronary button technique. The CVG concept evolved into preconstructed composites, initially with a mechanical valve, followed by biologic valves as an option. With a mechanical and tissue option, the indications for the type of CVG used are the same as those for a valve replacement (e.g., mechanical valves favored in younger patients because of durability, tissue valves in older patients or when lifelong anticoagulation is not a reasonable option).

Balancing the desire for a durable valve or root replacement with avoidance of lifelong anticoagulation led to a number of innovative techniques. Work by Lower and Shumway and promoted by Ross resulted in the eponymous Ross procedure. This technique is an autotransplantation of the pulmonary valve into the aortic position and subsequent replacement of the pulmonary artery root with a cadaveric homograft. Although the procedure never gained popularity in adult patients, it remains a viable alternative, especially when performed in high-volume environments. An alternative to the Ross procedure is replacement of the aortic root with a cadaveric homograft, notably in the setting of aortic valve endocarditis with destruction of the aorta annulus. Both of these procedures have the theoretical advantage of the lack of need for anticoagulation as well as an increase in durability compared with a tissue valve. However, both procedures are technically challenging, and the outcomes are dependent on the experience of the surgeon.

Dilatation of the aortic root or of the sinotubular junction because of an ascending aortic aneurysm may result in valve insufficiency in the face of normal valve leaflets. In this setting, the replacement of the normal valve while addressing the aortic root or ascending aorta seems like overkill. With sinotubular junction dilatation alone, replacement of the ascending aorta with a downsized graft may be sufficient to restore the aortic valve competency. With root dilatation and an anatomically normal valve, two valve-sparing approaches have been popularized: the remodeling technique and the reimplantation technique, championed respectively by Yacoub and David. Miller has summarized the techniques, referenced as David I through V (Table 102.4). Although expansion on each of the valve-sparing techniques is beyond the scope of this chapter, Miller summarizes the differences between the Yacoub remodeling and David reimplantation technique by the number of suture lines; remodeling employs two aortic suture lines, and reimplantation employs three. Both techniques use a Dacron graft as the neoaorta, and both, as previously mentioned for root replacements, require reimplantation of the coronary ostia. There is an exception to the comment that the coronaries are always reimplanted (i.e., the Florida sleeve technique where "slots" are made on the Dacron graft to accommodate the coronaries).

TABLE 102.4 Miller Classification of David Valve-Sparing Root Replacement

NAME	CLASSIFICATION	DESCRIPTION
David I	Reimplantation	Implantation in cylindric tube graft
David II	Remodeling	Classic Yacoub
David III	Remodeling	David II combined with aortic annuloplasty
David IV	Reimplantation	David I with 4-mm larger graft and plication at the sinotubular junction
David V	Reimplantation	David I with 6- to 8-mm larger graft and plication at sinotubular junction and annulus to create pseudosinuses

Adapted from Miller DC. Valve-sparing aortic root replacement in patients with the Marfan syndrome. *J Thorac Cardiovasc Surg.* 2003;125:773-778.

Open surgery of the descending thoracic aorta. Open surgical repair of thoracic aortic pathology has changed dramatically since the introduction of endovascular techniques. Although TEVAR has a predominant role in the management of thoracic aortic disease, there remain clinical scenarios in which knowledge of open approaches to the thoracic aorta is an important part of the surgeon's armamentarium. As mentioned previously, TEVAR may not always be appropriate or doable for some TBADs and, with a few exceptions, is not applicable to patients with Marfan disease or other connective tissue disorders. Issues regarding spinal cord protection and intraoperative monitoring are pertinent to open and endovascular techniques. Considerations specific to open surgery include the need and approach to distal perfusion ("clamp and sew," left heart bypass, CPB) as well as access. Many of the issues and considerations with open thoracic aortic surgery also pertain to TAAAs (see later).

Hemodynamic monitoring, specifically invasive arterial lines, during open repair of thoracic aneurysms and dissections is required and may necessitate transducing from both upper and lower body sites, depending on the surgical plan. Pulmonary artery catheterization is not typically helpful during the intraoperative period but can be useful in postoperative management. Use of TEE is reasonable in open surgery (as well as TEVAR) and carries a class IIa recommendation. A second class IIa monitoring recommendation relates to spinal cord perfusion, acknowledging the potential for the devastation of spinal cord ischemia after surgery on the thoracic aorta. Although not a therapeutic modality, motor or somatosensory evoked potential monitoring can help guide therapy and alterations in intraoperative management.

Avoidance of spinal cord injury secondary to ischemia is paramount in surgery of the thoracic and thoracoabdominal aorta for both open and endovascular approaches. Adjuncts used include cerebrospinal fluid (CSF) drainage, distal perfusion (either left heart bypass or CPB with femorofemoral cannulation), hypothermia, and pharmacotherapeutics. The rationale for CSF drainage is to increase spinal cord perfusion pressure (SCPP) by lowering CSF pressure. By definition, SCPP is as follows:

$$\text{SCPP} = \text{Mean distal aortic pressure} - (\text{CSF pressure} + \text{Central venous pressure})$$

Thus, SCPP can be favorably increased with increases in distal aortic pressure, decreases in CSF pressure (by drainage), and decreases in central venous pressure. Management of the CSF drain varies between setting a limit of CSF pressure (e.g., 10–15 mm Hg) to draining at a constant rate (e.g., 10–20 cc/h). Whichever approach is used, two things must be remembered. First, in instances of acute changes in neurologic status, an immediate drainage of 10 to 20 cc of CSF may salvage the spinal cord. Second, the two other variables related to SCPP—namely, mean aortic pressure and central venous pressure—can also be manipulated to maximize SCPP. CSF drainage is not innocuous, with almost 10% of patients developing a postdural puncture headache and a 2.8% reported risk of intracranial hemorrhage, the majority being subdural hematomas.[27]

Maintenance of distal aortic pressure and perfusion of visceral branches (including collaterals to the spinal cord) can be supplemented with circulatory support. For procedures of the thoracic aorta associated with dissection, CPB may be preferable because it provides not only circulatory support but also a mechanism for temperature regulation and rapid volume infusion. For both thoracic and thoracoabdominal procedures, the use of hypothermic circulatory arrest has been championed because of the elimination of the need for proximal and sequential aortic clamping (and the periaortic dissection required), easy proximal access to the arch, a bloodless field, and the ability to return all shed blood back to the perfusion circuit.

Open surgical repair of thoracoabdominal aortic aneurysms. For TAAA repair, an incision entering both the thoracic and abdominal compartments is required, representing a significant physiologic stress. For this reason, preoperative workup may be more extensive, including pulmonary function tests and more intense evaluation of cardiac function. Although repair can be performed with a clamp-and-sew technique, most high-volume centers perform repair with either left heart bypass or full CPB with hypothermic arrest. This approach is specifically advantageous for extent II TAAAs that do not have a safe location for clamping the most proximal aorta.

As in descending thoracic aortic procedures, paraplegia is an uncommon but feared complication of TAAA repair. Mortality after TAAA repair is significantly increased should paraplegia develop. The risk of paraplegia is increased with extent II TAAA, TAAA associated with AD, acute presentations, or previous infrarenal aortic surgery. Increase in SCPP, as previously discussed, may be protective. Other approaches to maximize spinal cord perfusion include intercostal artery reimplantation and maintenance of central perfusion. Strategies to decrease the metabolic rate of the spinal cord may include preoperative steroids, the use of a naloxone drip, moderate hypothermia (to 34°C), and injection of propofol just before clamping.

Construction of the visceral component of the graft may depend on the underlying cause for repair. For patients with degenerative TAAA, a Carrel patch may be considered for the reimplantation of the visceral vessels. This approach many simplify the operation and decrease the visceral ischemia time but may run the risk of future degeneration of the residual aorta and subsequent pseudoaneurysm formation. For those with connective tissue disorders or aneurysmal degeneration of a previous dissection, most would consider individual branch grafts to each visceral artery, thereby eliminating any suspect aortic tissue in the repair.

Open infrarenal abdominal aortic aneurysm repair. Open repair of AAA can be performed through a transabdominal or retroperitoneal approach. Advantages of the transabdominal approach include the ability to inspect the abdominal contents, supraceliac control without entering the thorax, and better exposure of the right iliac bifurcation and external iliac arteries. Potential disadvantages may include hernia formation, increased risk of bowel obstruction, and perhaps an increased risk of late aortoenteric fistula. With this approach, after the abdominal contents are inspected, the omentum and transverse colon are retracted cephalad, and the small intestines are retracted to the patient's right to expose the retroperitoneum and the ligament of Treitz. The ligament is taken down, and the duodenum is retracted to the right. A slip of tissue should be left attached to the duodenum for closure of this space after the repair. A self-retaining retractor can be helpful to maintain optimal exposure.

The posterior parietal peritoneum is incised to expose the aorta, and the dissection is carried proximally to expose the neck. The inferior mesenteric vein is generally encountered and should be identified, retracted, or ligated. As the dissection is carried cephalad, the left renal vein is encountered. This vein can be duplicated or travel behind the aorta; its course can and should be identified on preoperative imaging. The left renal vein can be retracted, and if needed, the adrenal and gonadal veins can be divided to provide more mobility of the left renal vein. Some have advocated for division of the left renal vein; if this is considered, the adrenal and gonadal veins must be left intact because they will subsequently provide the venous drainage of the left kidney. Proximal aortic control should be obtained at healthy aorta and with enough room to safely place sutures. Control can be either circumferential, which may allow a transversely oriented aortic occlusion clamp, or anterior and on either side of the aorta with the dissection carried down to the spine.

The dissection is then carried distally. If a tube graft is considered, it is safer to control the bilateral proximal iliac arteries to avoid injury to the iliac veins that travel directly behind the arteries and may be more densely adherent at the aortic bifurcation. If dissection and arterial control are required at or past the iliac bifurcation, care should be taken to avoid the ureters because they traverse anteriorly at this level.

Once the dissection is complete, the patient should be given heparin at 10 units/kg before clamping, with a goal activated clotting time (ACT) of 250 to 300 seconds. Once clamped, the aneurysm is opened and thrombus is removed. Back-bleeding from lumbar vessels should be controlled with suture ligatures. The origin of the inferior mesenteric artery (IMA) should be inspected. If back-bleeding is absent or brisk, it can also be suture-ligated; however, if back-bleeding is scant, the IMA should be preserved for possible reimplantation.

Appropriately sized polyester or polytetrafluoroethylene graft is then sewn into place, first proximally and then distally. The vessels are flushed to remove all debris, and then flow is slowly reestablished, making certain that the blood pressure remains stable. If a bifurcated graft is required, flow should be reestablished to one limb at a time. Heparin is then reversed if needed, hemostasis is secured, and then the sigmoid colon is interrogated for ischemia visually and with a Doppler probe; if present, the IMA should be reimplanted with either a Carrel patch or interposition graft. The wound is closed in layers, starting with the aneurysm sac and then posterior parietal peritoneum to protect the repair from the intestines. The remainder of the incision is then closed in a standard fashion.

Retroperitoneal exposure is generally performed with the patient in a semilateral position and through an oblique incision to the tip of the 11th rib. The incision can be extended into the chest for more proximal control if needed. With this approach, the left kidney is usually left down for infrarenal exposure but can be retracted upward with the peritoneum for more proximal exposure.

Endovascular Aortic Repair

Endovascular abdominal aortic aneurysm repair. EVAR has nearly become the gold standard for repair for AAA since first reported in the English literature by Parodi and colleagues in 1991.[28] A number of generations of devices have been developed, tested, and replaced with updated versions throughout the world. The success of EVAR for the treatment of AAA rests heavily on the interaction of the aortic stent graft and its seal and fixation zone within the aorta. For all endovascular procedures, certain principles apply, beginning with careful planning and correct sizing based on device-specific manufacturer instructions for use (IFU). Evaluation of access vessels (typically the common femoral or external iliac arteries) ensures adequate diameter as well as noting the presence of tortuosity and calcification. Verifying healthy arteries will allow for percutaneous access, performed by accessing the anterior noncalcified surface of the common femoral artery. Deployment of closure devices (if used) occurs before placement of the larger-bore sheaths required for stent graft delivery. Questionable access vessels may require open femoral exposure, with or without a conduit to the more proximal iliac artery. If a conduit is used, a 10-mm diameter will generally ensure passage of the delivery device. Once open access is obtained, stiff wires should be placed and used for endograft delivery. Limiting radiation exposure is paramount, and the recent implementation of image fusion (projection of preoperative CTA scan onto two-dimensional [2D] intraoperative fluoroscopic images [2D-3D fusion imaging]) demonstrates a reduction in exposure. Device configurations will vary by manufacturer. Many devices will have a bare-metal component that crosses the renal/visceral aortic segment and assists in device fixation (prevention of distal device migration). Devices can be constructed of woven polyester or polytetrafluorethylene, with either a stainless-steel or nitinol-metal framework. Many devices will have a bare-metal component that crosses the renal/visceral aortic segment and assists in device fixation (prevention of distal device migration). Devices are typically Y-shaped and will require placement of at least one additional iliac extension piece. The devices are inserted in a delivery system and then deployed once their location in the correct portion of the aorta is ensured. When the endograft placement is complete and balloon molding is performed, a final angiogram is obtained to investigate the presence of endoleaks. Closure of open incisions is standard after reversal of heparin. For percutaneous access, sheaths are removed over a wire as the sutures are secured. Maintaining wire access at this point is important should there be either an iliac artery injury requiring vascular control and/or endovascular repair or the need for placement of an additional closure device. Wires can then be removed after satisfactory hemostasis.

Postoperative evaluation of a successful EVAR includes serial CT scans and/or color duplex ultrasonography, looking for aortic sac diameter or volume, graft migration, and endoleaks. Surveillance imaging is generally recommended at 1 month, 6 months, 12 months, and yearly thereafter provided a stable examination. Because of the need for ongoing surveillance, patients who may be unwilling or unable to undergo postoperative imaging may not be appropriate candidates for EVAR.

When identified, endoleaks are classified as follows:

- Type 1A (proximal seal zone)
- Type 1B (distal seal zone)
- Type 2 (retrograde flow from lumbar and/or IMAs)
- Type 3 (component separation)
- Type 4 (fabric porosity)
- Type 5 (expanding aneurysm without demonstrable blood flow)

Type 1 and 3 endoleaks require repair. Type 2 endoleaks are common early after EVAR, with most resolving by 1 to 12 months. Management of persistent type 2 endoleaks is controversial, with most favoring observational management in the absence of sac growth. If sac growth occurs after EVAR with an otherwise stable type 2 endoleak, delayed type 1 or 3 endoleak may be the underlying culprit.

For infrarenal AAA, reported outcomes for open abdominal aortic repair vary from 1% to 4% for infrarenal repair performed in centers of excellence to 4% to 8% noted in statewide or nationwide databases.[23] Complications associated with open repair occur in 15% to 30% of patients. Both early mortality and complication rates are better with an endovascular approach to AAAs, although this may represent a selection bias. The UK EVAR trial investigators randomized 1252 patients with AAAs larger than 5.5 cm for elective open repair versus EVAR, and although the 30-day mortality rate was favorable for EVAR (1.8% vs. 4.3%, $P = 0.02$), this benefit was lost by the end of the study.[29] Additionally, EVAR was more costly, in part due to increased rates of graft-related complications and need for reintervention. A similar study by the Dutch Randomized Endovascular Aneurysm Management (DREAM) trial group found that early advantages of EVAR had disappeared by the 2-year follow-up mark.[30]

More recent long-term outcomes, though, have begun to call into question the durability of EVAR. The long-term follow-up from most of the randomized prospective trials evaluating open and EVAR has demonstrated that patients undergoing EVAR are at risk for having a higher reintervention rate than those who underwent open surgery. In fact, the early outcomes favoring EVAR resolved by 6 months postoperatively, and an increase in aneurysm-related mortality was observed at 4 years.[31] Crossover occurred at 6 to 8 years and was partially due to an increase in the rate of ruptured AAA.[32]

Endovascular approaches to the thoracic aorta. There have not been any randomized controlled trials to compare endovascular to open repair of the thoracic aorta, but nonrandomized studies, meta-analyses, and comparisons to historical data have suggested a decreased incidence of perioperative mortality and morbidity, including paraplegia. In the FDA phase II trial of the GORE TAG device, Makaroun and colleagues documented mortality rates of 1.5%, 1.5%, and 0% at 30 days, 1 year, and 2 years, respectively.[33] Early major adverse events included stroke (4%) and paraplegia (3%), which compared favorably with historical numbers. At 5 years, the aneurysm-related mortality was 2.8% in the endovascular patients versus 11.7% in the open controls, although there was no difference when considering all-cause mortality (68% survival in the endovascular group vs. 67% in the open group). A meta-analysis by Cheng and colleagues of TEVAR versus open surgical repair showed a reduction in 30-day and 1-year all-cause mortality (odds ratio of 0.44 and 0.73, respectively), with this reduction in all-cause mortality lost beyond 1 year.[34] The overall stroke rate was similar between the two groups. This meta-analysis revealed the primary benefit of TEVAR over open surgery to be a significant reduction in the risk of paraplegia and paraparesis. Thus, at least in the early follow-up period, reductions in all-cause mortality and complications favor TEVAR, especially in high-surgical-risk patients with suitable anatomy.

Considerations for suitable anatomy include appropriate landing zones with possible coverage of the left SCA, vertebral artery anatomy, angulation and tortuosity of the aorta, size and amount of disease in the planned access arteries, and concurrent AAA. For landing zones, it is usually adequate to obtain a 2- to 3-cm seal zone proximally with extension if the aorta is particularly tortuous or angulated. As shown in Fig. 102.3, there are five potential landing zones for the ascending aorta, arch, and proximal descending thoracic aorta:

- Zone 0: proximal to the innominate artery
- Zone 1: proximal to the left common carotid artery
- Zone 2: proximal to the origin of the left SCA
- Zone 3: proximal descending thoracic aorta less than 2 cm from the left SCA
- Zone 4: greater than 2 cm from the left SCA and extends to the proximal portion of the descending aorta (level of T6 vertebral body)

Proximal lesions of the thoracic aorta may require coverage of the left SCA (i.e., zone 2 landing). In patients with previous coronary revascularization where an in situ left internal mammary was used as a conduit, it is essential to perform left SCA revascularization before zone 2 coverage to prevent myocardial ischemia. The overall reported incidence of left SCA coverage in single-center studies ranges from 23% to over 40% incidence with or without left SCA revascularization. In a multicenter study, the European Collaborators on Stent/Graft Techniques for Aortic Aneurysm Repair (EUROSTAR) reported 26% of 606 requiring left SCA coverage.[35] In the EUROSTAR study, there was a 2.5% incidence of paraplegia or paraparesis and a 3.1% incidence of stroke. Multivariate regression analysis demonstrated a correlation between spinal cord ischemia and SCA coverage without revascularization (odds ratio 3.9, $P = 0.027$). Paraplegia or stroke occurred in 8.4% of patients with left SCA coverage when prophylactic revascularization was not performed, compared with 0% when it was performed. Feezor and colleagues found that in their TEVAR patients who had strokes, 78% of strokes were in the posterior circulation territory, highlighting the importance of evaluating the vertebral artery anatomy preoperatively to determine those who might be at a higher risk for posterior circulation strokes with acute coverage of the left SCA.[36] All of the patients in the Feezor and colleagues study had coverage of zones 0 to 2, and only one of the six patients had preemptive carotid-subclavian bypass.

Buth and colleagues also found that in addition to SCA coverage, the use of three or more stents had a significant impact on the development of spinal cord ischemia (odds ratio 3.5, $P = 0.43$).[35] A meta-analysis by Cooper and colleagues reported an incidence of spinal cord ischemia of 2.3% without SCA coverage versus 2.8% with SCA coverage (pooled odds ratio 2.39).[37] Because the thyrocervical trunk branches and vertebral artery contribute to the anterior spinal artery, revascularization may be important for prevention of spinal cord ischemia. Woo and colleagues reported that their indications for left subclavian revascularization included a dominant left vertebral artery; a stenotic, atretic, hypoplastic, or absent right vertebral artery; an incomplete vertebrobasilar system; a history of arm ischemia; and a patent left internal mammary artery–left anterior descending artery (LIMA-LAD) bypass. In a single-center comparison, the reported incidence of spinal cord ischemia with TEVAR was less compared with open repair (6.7% vs. 8.6%, respectively), although it did not reach statistical significance.[38]

Other proposals to reduce the risk of spinal cord ischemia, other than selective left SCA revascularization, as mentioned earlier, include avoiding intraoperative and postoperative hypotension, spinal fluid drainage, and naloxone infusion. It is important to have both preoperative and postoperative protocols in conjunction with your anesthesia team to achieve this. If the patient needs treatment of both abdominal and thoracic aortic pathology, staging the procedures should allow adequate collateralization to develop. The EUROSTAR study found that concomitant open abdominal aorta surgery had a significant impact on the development of spinal cord ischemia (odds ratio 5.5), presumably from interruption of the IMA and/or intercostal and lumbar artery branches.

Finally, another consideration to determine the feasibility of TEVAR is adequacy of access vessels. Ideally, an access vessel measuring at least 8 mm in diameter will be adequate for most device delivery systems. The size of the thoracic aorta generally requires larger endograft devices compared with EVAR and will therefore require larger sheath access. It is important to have imaging of the abdominal aorta and iliac arteries to determine the best access vessel based on size, disease, and tortuosity. If the femoral and/or external iliac arteries are not adequate, then a common iliac conduit graft can be considered. In rare cases, if neither iliac system is adequate, then an aortic conduit may be feasible. A dreaded complication of TEVAR is disruption of the iliac vessel upon removal of the access sheath, requiring either endovascular or open repair, usually with temporary endovascular balloon inflation for control of hemorrhage.

Fenestrated and branched aortic endografts. Endovascular treatment of aortic disease in regions of the aorta that abut or cross significant vessels becomes more difficult and has led to the development of fenestrated aortic endografts and branched aortic endografts. This nomenclature defines a structural addition to conventional endografts that allows for a reinforced hole to be "cut" into the stent graft, known as a fenestration, or an actual branch to be attached to the endograft. The use of these modifications was first employed to treat short-neck infrarenal aortic aneurysms. This device, called the Z-Fen device (Cook Medical, Bloomington, IN), was the first commercially available, custom-designed stent graft available in the United States. It allowed for custom-placed fenestrations to be placed on a stent graft in order to allow for continuous perfusion of the renal arteries and superior mesenteric artery—extending the proximal landing and seal zone of an EVAR device. Five-year outcomes for these devices showed excellent durability with continued 5-year renal artery patency of 98%, freedom from mortality of 91%, and no aneurysm ruptures or conversion to open repair. Unfortunately, as we have observed in most aortic endograft treatments, there was only a 63% rate of freedom from reintervention. Based on the success of this technology, the extent of treatment has been significantly advanced. Treatment of more extensive AAAs and TAAAs has been possible. Technologic approaches to this have been based on concepts that involved custom-made devices as well as off-the-shelf options. There has been tremendous success using these types of grafts worldwide, with some of the greatest experience arising within the United States through physician-sponsored research programs. Similar to the 5-year outcomes for the Z-Fen trial, outcomes from the physician-sponsored programs have demonstrated excellent long-term results with regard to aneurysm exclusion and branch patency but high rates of reintervention to achieve these results.[39,40] At the time of writing this chapter, no commercially available option is available within the United States, but the Gore TAMBE (Gore Medical, Flagstaff, AZ), a four-vessel off-the-shelf option, has completed enrollment and is awaiting final data collection before submission to the FDA.

Similar to the visceral segment of the aorta, fenestrated and branched technology is actively being evaluated for treatment of aortic disease that involves the aortic arch. The device designs have varied to incorporate anywhere from one to three arch branches. Single-branch and dual-branch designs require a hybrid approach with revascularization of the left subclavian or both the left carotid and SCAs. Early experience with multibranch designs demonstrates a significant learning curve, with anatomic constraints and risk of stroke limiting some of their clinical applicability.[41] Various graft designs and deployment systems are currently under investigation globally. Within the United States at the time of writing of this chapter, the Gore TBE single-branch device is commercially available for incorporation of the left SCA. Expansion of this approval to zone 0 landing with incorporation of the innominate artery and debranching of the other great vessels is anticipated.

Ruptured abdominal aortic aneurysms. Ruptured AAAs deserve special attention. Approximately 15,000 annual deaths from ruptured AAAs occur in the United States. In ruptured AAAs where it would be ideal to treat with an endovascular approach, there has not been any statistical evidence of a short-term benefit of one approach versus another. In one European trial, comparison between open and EVAR showed no difference in operative mortality (39% vs. 35%, respectively) or 90-day mortality (42% vs. 40%).[42] In the IMPROVE (Immediate Management of the Patient With Ruptured Aneurysm: Open Versus Endovascular Repair) trial, there was no difference in 30- or 90-day mortality, but there was an advantage for EVAR at 4 years (42% vs. 54%); once again, however, this advantage was gone by 7 years.[43] Interpreting these trials is challenging because intention to treat and treatment received may not align, thereby biasing the conclusions. Post hoc analysis of these data suggests that those who were able to receive an endovascular repair enjoyed better outcomes; therefore, it is the recommendation of many to consider an "endovascular-first approach."

Rapidly and effectively treating ruptured AAA requires trained personnel, access to endovascular inventory, and standard standardized protocols. Examples of such may include systems for rapid transport to an operating room (OR) with both open surgical and endovascular capability, minimal preoperative testing and imaging, and placement of an aortic occlusion balloon. The latter should be placed before induction of anesthesia because it may support blood pressure regardless of the type of repair offered. For patients amenable to EVAR for ruptured AAA, outcomes may be improved if general anesthesia is avoided altogether and the procedure is performed under local anesthesia.

Of note, many patients with ruptured AAA present with significant comorbidities or severe acutely deteriorating clinical condition. For this reason, over the past two to three decades, many scoring systems have been proposed to predict nonsurvivability and therefore consider comfort care instead of attempts at definitive repair. These scoring systems either were developed before the advent of EVAR or have not been validated with contemporary care. The University of Washington scoring system is one of the few that predicts futility rather than increased mortality risk and therefore may be more useful.[44] A recent institutional study demonstrated that only a very small proportion of patients met futility criteria with this scoring system. Additionally, outcomes outperformed all predictive models, thereby raising concerns about the clinical usefulness of such scoring systems.[45] Thus, each patient should be judged individually to determine suitability for intervention and definitive repair.

With increasing specialization of vascular surgery and expansion of EVAR for ruptured AAA, many hospitals are no longer equipped to provide care, thereby necessitating the need for transfer of these critically ill patients. Use of transfer appears to be increasing, creating additional challenges for timely intervention. When available, local care may represent the best treatment because although operative mortality is better for transferred patients, overall mortality is worse. This paradox is most likely explained by selection bias of those who are clinically stable to receive treatment once they arrive at the receiving hospital. In fact, approximately one in seven patients who are transferred does not receive treatment, which may be a result of clinical deterioration, severe comorbidities that may not have been recognized at the sending hospital, or patient refusal. To address this, current guidelines[23] provide recommendations for transferring patients with ruptured AAA to optimize the transfer process and provide the greatest opportunity for definitive repair in transferred patients.

OCCLUSIVE DISEASE OF THE AORTA

Symptomatic arterial occlusive disease is much more common in small- and medium-sized arteries; however, unusual variants of occlusive disease in the thoracic and abdominal aorta should be recognized and treated appropriately to avoid substantial morbidity and mortality. Although typical lower extremity symptoms such as claudication, ischemic rest pain, or ischemic tissue loss may be present in patients with aortic occlusive disease, the symptoms can be much more protean and are easily misdiagnosed or inappropriately treated. There are unique disease patterns and clinical scenarios with occlusive disease of the aorta that can be managed successfully with excellent long-term results if diagnosed promptly and addressed expeditiously. The widespread availability and use of CTA has made diagnosis of these aortic conditions more common, and medical, endovascular, and traditional open surgical options may be employed in treatment, depending on the severity and acuity of the disease.

Coral Reef Aorta

Coral reef aorta is defined by the presence of irregular, heavily calcified aortic plaques that protrude into the aortic lumen. These plaques may be up to 70% calcium, whereas atherosclerotic plaques more generally are typically less than 15% calcium. There is a slight female predominance in the literature, with 62% of reported cases involving females. The cause of these calcified lesions is unknown; however, the appearance is characteristic and unmistakable on CT angiogram (Fig. 102.5). Coral reef plaques may appear anywhere in the thoracic or abdominal aorta but are most commonly localized to the visceral or infrarenal aorta.

Diagnosis is often delayed by a symptom complex that can be rather vague, and patients can present with claudication, renovascular hypertension, intestinal angina, or emboli to the lower extremities (Table 102.5). Acute presentations with renal or visceral infarction or acute limb ischemia may be particularly challenging to manage, given the urgency of revascularization and the complexity of treating the lesion. An initial ankle-brachial index (ABI) or arterial duplex is often obtained but is typically nonspecific, demonstrating only arterial occlusive disease localized to the aortoiliac segment. After noninvasive testing, patients with evidence of severe occlusive disease in the abdominal aorta should typically undergo CTA of the abdomen and pelvis as the next step in evaluation. CTA with an appropriately timed contrast load will demonstrate the extent of the calcified plaque and is almost always adequate for planning definitive treatment.

As routine abdominal CT scanning becomes standard for evaluations of vague abdominal pain and major trauma, coral reef plaques may be noted as incidental findings in asymptomatic patients. The majority of reports in the literature, however, have focused on patients with severe symptoms, and on this basis, the coral reef plaque is assumed to have a more malignant course. Although an asymptomatic coral reef plaque can certainly be treated conservatively with observation, antiplatelets, and statins, presenting symptoms are often severe enough that surgical or endovascular treatment is warranted.

Treatment algorithms in the past have focused exclusively on open surgical options, employing either extraanatomic bypass or aortic endarterectomy; however, endovascular adjuncts may certainly be employed, particularly in patients with multiple comorbidities who may not tolerate an open surgical approach to the visceral segment. Addressing the coral reef aorta is particularly complicated because it usually involves multiple vessels in the visceral segment. A treatment plan must restore flow to all of the compromised visceral vessels as well as the lower extremities. And although endovascular options may be appealing from the standpoint of a quick postoperative recovery, they typically play an adjunctive role. Bulky, rock-hard coral reef plaques do not usually angioplasty well, potentially leaving residual narrowing, a crushed stent, or a catastrophically ruptured aortic wall. Much of the existing literature has focused on aortic endarterectomy as the primary treatment for coral reef plaques. This approach has the potential to completely clear the disease process from the aorta and all of the involved visceral vessels with a durable result that may last the remainder of the patient's life. The surgical approach is, however, quite challenging and should be attempted only by surgeons who

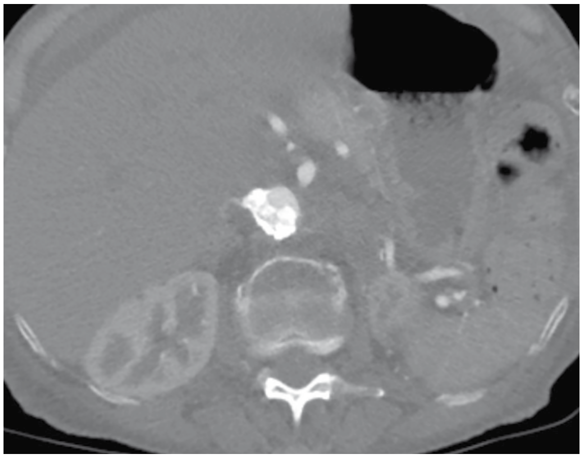

FIGURE 102.5 A large coral reef plaque is seen at the level of the renal arteries. This patient presented with renovascular hypertension and was treated with an ilio-renal bypass.

TABLE 102.5 Symptoms of Coral Reef Aorta

Presenting Symptoms	
Intermittent claudication	44%

Ischemic tissue loss	2%
Refractory hypertension	36%
Renal insufficiency	12%
Intestinal angina	22%

have extensive experience with open surgical reconstruction of the visceral aorta and mesenteric vessels. In practice, however, there is probably not a one-size-fits-all approach to these lesions, and some combination of endarterectomy, bypass, or even angioplasty and stenting may be employed.

Endarterectomy is most easily applied in patients with plaques confined to the infrarenal aorta, where a direct transperitoneal approach can provide exposure of the entire involved aortic segment to facilitate clamping, aortotomy, and endarterectomy.[46] Unfortunately, most of these plaques involve the visceral vessels, and a more complicated retroperitoneal approach to this portion of the aorta is required. This is most often described as a thoracoabdominal incision with complete mobilization of the abdominal contents to the patient's right to gain exposure from the supradiaphragmatic aorta to the bifurcation. A trapdoor aortotomy is then created to facilitate endarterectomy and complete clearance of the plaque from each of the visceral orifices (Fig. 102.6). In practice, endarterectomy may be combined with bypass to the visceral vessels or even replacement of a segment of the aorta if adequate end points cannot be obtained or the remaining aorta is too friable to close securely.

Alternative strategies can be considered in patients who are poor candidates for thoracoabdominal exposure with its attendant prolonged visceral ischemia, blood loss, and cardiopulmonary complications. These approaches may involve extraanatomic bypass to the visceral vessels or lower extremities or employ endovascular adjuncts.[47] Axillofemoral bypass, for instance, may be a sound, if imperfect solution for frail patients presenting primarily with lower extremity occlusive symptoms. Operative debranching with retrograde bypass to one or more of the visceral vessels with stent grafting through the primary aortic lesion may offer another somewhat less definitive but also less morbid approach that can avoid long visceral ischemic times in patients with appropriate anatomy.

Not all patients necessarily require revascularization of all four visceral vessels, and a targeted approach to the most severe disease in the most salvageable vessels can allow for a limited operation that is still durable enough for an older patient with multiple comorbidities. For instance, in a patient with severe hypertension and declining renal function with heavily calcified renal involvement, an extraanatomic renal artery bypass can alleviate the short-term problem. Fig. 102.5 illustrates a patient with a coral reef plaque involving the renal arteries but with preserved flow through the visceral segment. In this case, a right ilio-renal bypass restored flow and eliminated the immediate risk of renal failure. Hepato-renal or spleno-renal bypass could also be considered if the celiac artery is patent and uninvolved. A similar approach may be considered for the superior mesenteric artery in patients with chronic mesenteric ischemia, with antegrade or retrograde bypass configurations.

Stent grafting through the affected segments of the aorta can restore flow; however, rupture of the treated segment or poor expansion of the graft are real risks, and balloon-expandable stent

grafts are often employed to obtain maximal radial force and seal off any perforations caused by angioplasty. Aggressive attempts to restore a completely normal aortic lumen with a stent graft are not warranted, and the goal would be to create a channel through the involved segment that is large enough to alleviate the symptoms and perfuse the viscera (Fig. 102.7).

Shaggy Aorta

Extensive irregular thrombus lining the aorta, the so-called "shaggy aorta," is not infrequently a source of acute embolic events to both the viscera and the lower extremities. Typically, shaggy aorta occurs in patients with extensive aortic atherosclerosis and surface degeneration, resulting in exposure of friable plaques or the accumulation of irregular, chronic thrombus (Fig. 102.8). This pathology may involve any segment of the aorta but more commonly is diffuse, with involvement of multiple segments. It may occur in isolation or accompany aneurysmal disease, which can significantly complicate an aneurysm repair. Diagnosis of this entity is increasing as more contrasted CT scans are ordered as a part of the workup for nonspecific chest and abdominal pain.

Shaggy aorta may be the source of spontaneous emboli to any of the aortic branches, depending on the areas of involvement. Showers of cholesterol microemboli can cause blue toe syndrome, but these microembolic events can also result in acute renal failure or bowel ischemia. Accumulated mobile thrombus may result in large-vessel occlusion of major visceral or lower extremity branches and result in an acute presentation with bowel or limb ischemia. Microembolic events may be treated expectantly, but larger macroembolic events need to be treated expeditiously with open embolectomy or percutaneous mechanical thrombectomy. Postevent, most patients will be systemically anticoagulated; however, longer term, only dual-antiplatelet treatment is recommended for prophylaxis against secondary events. Statins are indicated both from the standpoint of preventing progression of atherosclerosis generally and for plaque stabilization.

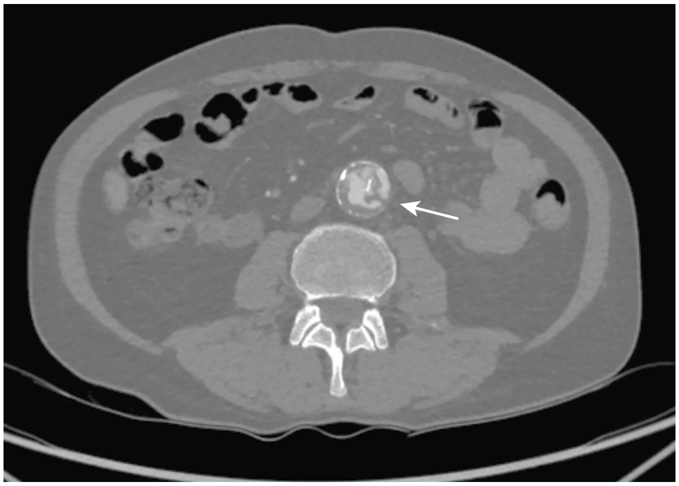

FIGURE 102.8 This patient demonstrates a severe shaggy aorta syndrome in the infrarenal segment *(arrow)*.

Most of the literature regarding shaggy aorta is, however, concerned with its potential for complications during either open or EVAR or other percutaneous procedures that may traverse the aorta. Aneurysm repair in any segment of the aorta is fraught with complications in patients with a shaggy aorta. Open TAAA repair in the presence of a shaggy aorta has an approximately 30% risk of major complication or death. Risks of spinal cord ischemia and acute renal failure, in particular, are markedly increased in the presence of shaggy aorta. Infrarenal aortic repair is also a higher risk in the presence of shaggy aorta. A recent large institutional series demonstrated a roughly 11% rate of shaggy aorta syndrome in 447 patients presenting for elective AAA repair.[48] This series documented a fourfold increase in morbidity and mortality for patients with a shaggy aorta. One might assume that EVAR would carry a much higher risk in patients with a shaggy aorta because of the intraarterial manipulation with wires and catheters; however, open aortic repair carried a substantially increased risk as well. Embolic events were much more common in patients with a shaggy aorta, presumably accounting for much of the increased overall mortality.

The substantially increased risk profile of patients with a shaggy aorta should be considered carefully before advising any patient to undergo aneurysm repair. Patients with a shaggy aorta have a significantly reduced life expectancy overall, regardless of which type of repair is chosen. Given the increased risk of immediate perioperative embolic events and the overall poor long-term survival of the patient cohort, repair should only be considered when the risk of rupture is substantial in the short term. Some authors recommend that the size threshold for elective repair of infrarenal aneurysms in these patients should be at least 6 cm and possibly larger.

If open repair is considered, procedural modifications should be made to minimize the risk of a catastrophic embolic shower. The clamp site should be chosen to avoid the worst areas of mobile thrombi. This may involve a supraceliac clamp if the pathology is mainly confined to the visceral segment, and care should be taken to minimize any movement of the clamp after initial application. Once the repair is completed, the proximal aorta should be flushed out onto the field to remove any debris around the clamp and back-flushed to remove as much distal debris as possible.

If CPB or left heart bypass is implemented for more extensive aortic arch or thoracoabdominal repairs, the site for arterial cannulation must be chosen carefully to avoid areas with extensive atherosclerotic plaque. A shaggy aorta should not be directly accessed, and axillary cannulation is generally preferable to femoral cannulation because retrograde flow across a shaggy aorta and into the cerebral circulation may result in a devastating stroke.

Atypical Aortic Thrombus

Patients with either inherited or acquired hypercoagulability may also develop more localized thrombus within the thoracic or abdominal aorta, which has a distinct appearance and presentation that is different from the shaggy aorta. This has been termed *atypical aortic thrombus* (AAT). This pathology almost always occurs in the descending aorta or visceral segment and has a characteristic appearance with a noncalcified eccentric thrombus protruding into the aortic lumen (Fig. 102.9A). AAT is distinct from thrombus with a cardiac origin or thrombus associated with aneurysmal disease and is unrelated to shaggy aorta, which occurs in the presence of extensive atherosclerosis. This phenomenon often occurs in a younger patient population in their 40s and 50s rather than the older patients with severe atherosclerosis presenting with either coral reef aorta or shaggy aorta. AAT is often associated with a hypercoagulable state or a significant smoking history, and malignancy should be high on the differential of patients presenting with AAT.

AAT almost always presents with macroembolization to large branch vessels and is identified on CTA as a part of a comprehensive embolic workup. It is often manifest as an eccentric plaque in the descending or visceral aorta that protrudes significantly into the lumen. Acute limb ischemia, renal emboli, or bowel ischemia must be addressed promptly with any number of surgical options, which may include embolectomy, bowel resection, percutaneous mechanical thrombectomy, or covered stenting, depending on the location, degree of ischemia, and the overall patient condition.

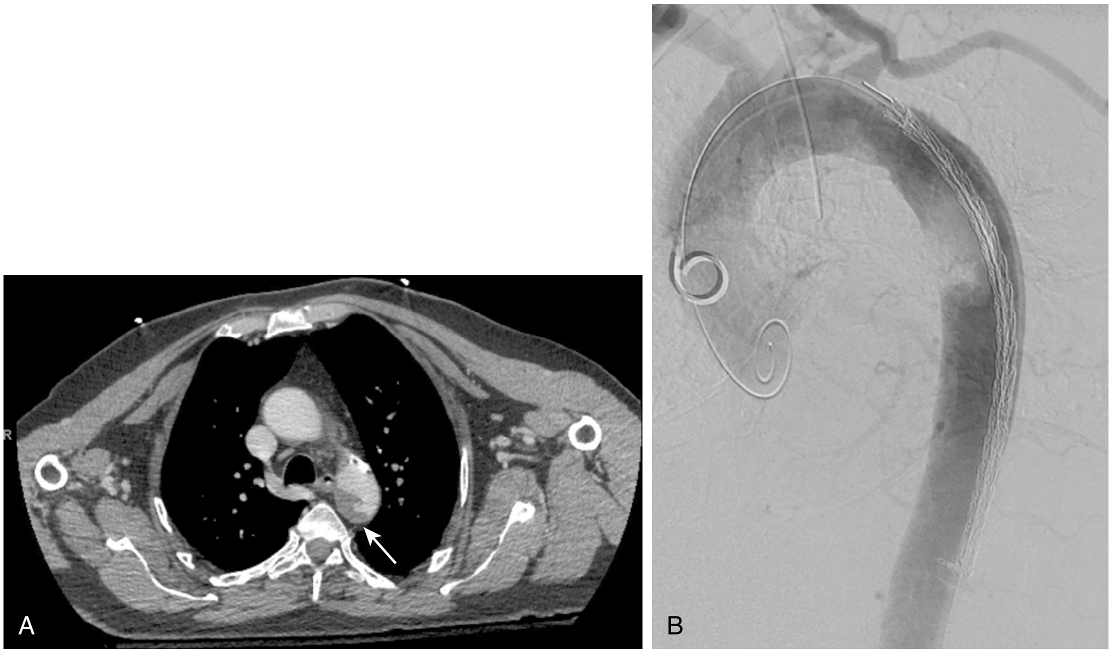

FIGURE 102.9 A patient with atypical aortic thrombus of the proximal descending aorta (A) underwent bilateral femoral-popliteal embolectomy followed by stent grafting over the aortic thrombus (B).

Once the acute ischemia has been dealt with, the source must be addressed, and various approaches have been described. The most obvious solution is trapping the thrombus behind an aortic stent graft (see Fig. 102.9B). However, this may not be applicable with thrombi that are near major visceral branches. Endovascular manipulation may risk additional embolic events, and thrombus may be displaced directly into nearby branches as the graft is expanded. For this reason, various treatments have been employed, ranging from simple systemic anticoagulation to systemic tissue plasminogen activator (tPA) or even aortotomy with direct thrombus extraction. Although a potentially morbid operation, aortotomy and thrombus removal eliminates any further risk of embolus. For a patient with a visceral-level thrombus and mesenteric and renal emboli, aortotomy with visceral embolectomy may offer the only chance to remove the offending aortic thrombus and restore visceral perfusion.

Aortoiliac Occlusive Disease

Atherosclerotic disease of the infrarenal aorta resulting in lower extremity symptoms such as claudication or ischemic tissue loss is more properly considered as aortoiliac disease because the atherosclerosis is rarely isolated to the abdominal aorta. Aortoiliac disease that develops chronically may be well tolerated because collateral networks can be extensive, and patients may have severe occlusive disease or aortic occlusion with only mild to moderate claudication.

This disease pattern is almost always localized below the visceral segment and develops over a period of years to decades. Risk factors mirror those for atherosclerotic disease more generally, including diabetes, hypertension, and hyperlipidemia; however, severe aortoiliac occlusive disease is most strongly associated with a smoking history.

A combination of physical examination findings and noninvasive vascular testing will usually identify patients with an aortoiliac pattern of disease, but a suggestive history and weak or absent femoral pulses may be sufficient to make a diagnosis. Symptomatology often includes buttock or thigh claudication and impotence, which, along with absent femoral pulses, constitutes the Leriche syndrome. Although moving straight to aortography is an option, most practitioners prefer cross-sectional imaging with CTA to plan a treatment course, which may be endovascular intervention, surgical bypass, or some combination of the two. Recommendations for treatment should be based on the extent of the disease and the patient's fitness to undergo a major surgical procedure. Although iliac atherosclerotic disease can almost always be addressed with an endovascular approach, extensive aortic involvement is often most durably treated with direct aortic reconstruction or extraanatomic bypass.

Traditionally, an aortobifemoral bypass was considered the gold standard for treatment of aortoiliac occlusive disease and was frequently performed for almost any pattern of disease involving the aorta or bilateral iliac arteries. More recently, iliac stenting has largely replaced aortobifemoral bypass for most iliac disease, including atherosclerosis that involves the distal aorta. Extension of the stents into the distal aorta, so-called "kissing stents," will address distal aortic pathology as well as iliac disease. Both balloon-expandable and self-expanding stents or stent grafts have been used successfully; however, stent grafts are increasingly used to both limit in-stent restenosis and avoid free rupture of the vessel, which can occur with angioplasty of heavily calcified arteries.

Total occlusion of the infrarenal aorta is the end point of severe atherosclerosis and represents the most challenging clinical scenario (Fig. 102.10). Endovascular approaches can be considered in patients who are poor surgical candidates, and an initial attempt to cross extensive occlusions and deliver a stent is not unreasonable. Stents can be extended up to near the level of the renal arteries, effectively raising the aortic flow divider to just below the renal arteries.

Ideally, a patient with an occluded infrarenal aorta should undergo aortic replacement with an aortobifemoral or aorto-biliac graft. The surgical procedure is somewhat more complicated because the occlusion often extends to the level of the renal arteries. Clamp application is at the suprarenal or, more commonly, the supraceliac location, and the aorta is opened, followed by removal of intraluminal thrombus with or without endarterectomy of bulky, calcified plaque. End-to-end anastomosis is then created for the inflow, and the distal anastomoses are commonly to the common femoral or profundafemoral arteries. If a transabdominal procedure is considered high risk because of cardiopulmonary issues or previous surgeries, an axillo-bifemoral bypass can be a lower-risk option. Although the long-term patency is not as good as with an aortobifemoral graft, the procedure is generally lower risk because it avoids a laparotomy, major blood loss, and a period of visceral ischemia.

Hypoplastic Aortic Syndrome

Hypoplastic aortic syndrome, or small aorta syndrome, is a variant of aortoiliac disease found in females with a relatively small distal aorta and iliac arteries characterized by early onset of ischemic symptoms in patients with a small-diameter distal aorta

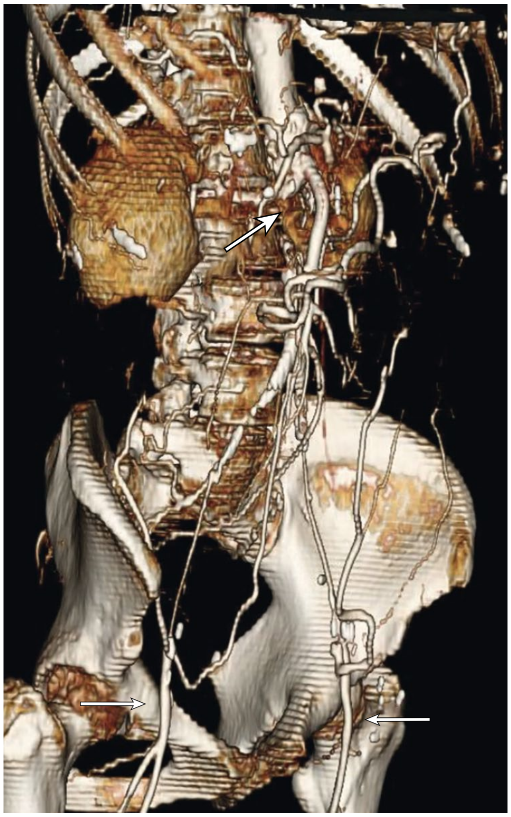

FIGURE 102.10 Chronic occlusion of the aorta just below the renal arteries is shown *(large arrow)*. There is reconstitution of the common femoral arteries via extensive collaterals *(small arrows)*.

and iliac arteries. These patients present in their fourth and fifth decades with severe symptoms and almost universally have an extensive smoking history. Whether this represents a truly separate pathologic entity or simply one end of a continuum in the size of the aorta and iliac vessels is unclear; however, it should be recognized that successful treatment may be much more challenging in these young patients.

Endovascular techniques are often employed initially but may lack durability, given the small size of the vessels, the extensive stenting that may be required, and the persistence of a smoking habit. Aorto-femoral bypass is often recommended as the preferred option in a patient population that is younger and presumably able to tolerate a more extensive operation. Bypass results may, however, also be suboptimal, given the small graft sizes needed to accommodate the smaller inflow and outflow vessels. Aggressive antismoking interventions, antiplatelet and statin therapy, and long-term graft surveillance are all key to a long-term successful outcome.

Aortic Sarcoma

Aortic sarcoma is a rare entity with a literature dominated by single case reports of patients presenting with advanced disease. It is instructive that 26% of patients with the disease are diagnosed postmortem, and 5-year survival is estimated at a dismal 9%. Larger pooled analysis of available cases, however, can shed some light on this challenging pathology.[49]

Patients with aortic sarcoma typically present with a constellation of symptoms that are often ascribed to other diagnoses. The most common is embolization to the extremities or visceral vessels; however, less specific complaints, such as constitutional symptoms, claudication, abdominal discomfort, hypertension, back pain, and anemia, are almost as frequent. Early diagnosis is rare in this setting, and even with adequate imaging, the diagnosis may not be obvious.

The most common histology is angiosarcoma, but there is a wide variety of histologic subtypes (Fig. 102.11), and the overall outlook is typically grim, with poor overall survival (Fig. 102.12) regardless of subtype. Ideally, complete resection with adjuvant radiation and/or chemotherapy may offer the best chance of long-term survival, but resection of a large segment of the aorta may require an extensive procedure. Sternotomy and circulatory arrest or thoracoabdominal exposure with aortic resection and replacement are very unappealing in a patient with aggressive disease and likely poor long-term outcome, but they can be considered in young patients with localized disease who are felt to be excellent surgical candidates. In most cases, however, palliation is the only option, and in this context, prevention of repeat embolic episodes will be helpful. Systemic anticoagulation with or without stent grafting over the embolizing lesion will typically be better tolerated than an open surgical resection, and patients may proceed with palliative chemotherapy or radiation shortly postoperatively.

CONGENITAL AORTOPATHY

Heritable thoracic aortic disease (HTAD) accounts account for approximately 20% of thoracic aortic aneurysms and can alter the recommendations for treatment and/or the expected clinical outcomes. Some of these are associated with multisystem features (known as *syndromic HTAD*), whereas other presentations are limited to the aorta (*nonsyndromic HTAD* or *familial TAA*).[3] Diseases involving HTAD can affect the entire aorta but most commonly present in the more proximal portions of the aorta. They can also present with either AD or aneurysm formation. There is a growing list of different HTADs that have been identified, and describing all of them is beyond the scope of this chapter. In addition, treatment guidelines for all of these are similarly outside

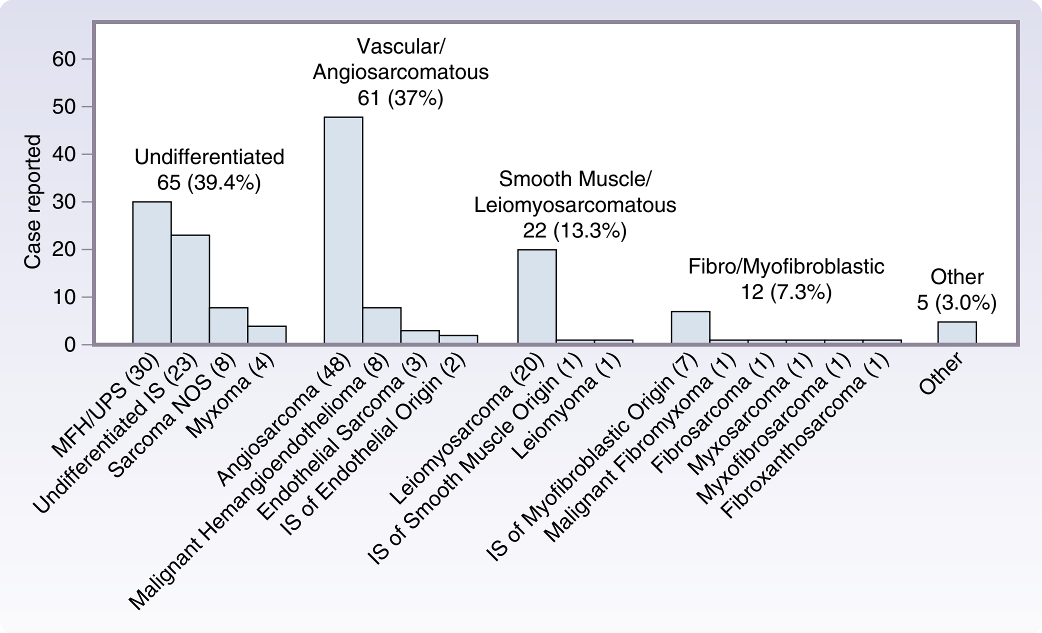

FIGURE 102.11 Cases reported by histology. "Other" includes two cases of chondrosarcoma, two cases of hemangiopericytoma, and one case of intimal sarcoma of rhabdomyosarcomatous differentiation. *IS,* Intimal sarcoma; *MFH,* malignant fibrous histiocytoma; *NOS,* not otherwise specified; *UPS,* undifferentiated pleomorphic sarcoma.

the focus of this chapter, but they have been well documented in recent guideline recommendations.[3] A brief review of a few of the most commonly encountered aortopathies follows. Although currently undergoing some scrutiny, the major intervention for patients with aortic disease secondary to a known aortopathy is conventional surgery because this does not rely on the stability of the aorta for the durability of its repair. Endovascular therapies have predominantly been limited to emergency situations, as a bridge to conventional surgery once the patient is stabilized, or in a hybrid fashion in which the landing/seal zones for the endografts occur in previously replaced aortic or aortoiliac segments.

Marfan Syndrome

Marfan syndrome is an autosomal dominant, age-related connective tissue disorder that is related to pathogenetic variations in the *FBN1* gene, which codes for the extracellular matrix glycoprotein fibrillin-1.[50] Nearly one-quarter of *FBN1* variants are de novo, and they frequently present with a more aggressive phenotype. It is highly penetrative and demonstrates substantial variability, with nearly 2000 genetic variants currently identified. Marfan syndrome affects all ethnicities but may have variable penetration. Marfan syndrome most frequently presents with enlargement of the ascending aorta, which places it at risk for continued growth as well as risk for acute dissection, as discussed earlier. Less commonly, Marfan syndrome can be associated with isolated thoracic aortic and AAAs. In addition to aortic abnormalities, Marfan syndrome presents with skeletal (pectus excavatum or kyphoscoliosis) and ocular manifestations (lens dislocation, retinal detachment, glaucoma). Diagnostic criteria were revised in 2010 and reported as the Ghent II criteria. These criteria incorporate physical examination findings of skeletal abnormalities paired with aortic changes, ocular abnormalities, family history, and identification of *FBN1* mutation. Familial screening is recommended for family members of those patients who present with Marfan syndrome, with 50% of the offspring being affected. Screening is performed with site-specific testing.

Murine models of Marfan syndrome have implicated transforming growth factor-β (TGF-β) signaling and the angiotensin II signaling cascade as possible contributors to the underlying pathophysiology. In some murine models, the use of angiotensin II receptor blockade (losartan) demonstrated effectiveness in preventing aortic aneurysm development. Historically, pharmacologic treatment with β-blockade (propranolol) in a small randomized trial prevented the growth of aortic root dilation in 10-year follow-up compared with those who did not receive the medication. Although the results from the mouse models suggested that losartan may be effective in preventing aortic expansion, despite initial enthusiasm, randomized trials comparing angiotensin receptor blocker (ARB) to β-blocker in patients with Marfan syndrome did not demonstrate any appreciable difference between the two. The addition of ARB to baseline therapy, which included β-blockers, demonstrated that the combination resulted in a reduction in growth rates.

Loeys-Dietz Syndrome

Loeys-Dietz syndrome (LDS) is an autosomal dominant connective tissue disorder that has been associated with aortic and other arterial abnormalities. These include arterial tortuosity, aneurysm formation, and AD. Similar to Marfan syndrome, LDS has additional nonaortic phenotypic expression, including craniofacial, skeletal, and cutaneous manifestations such as hypertelorism and bifid/broad uvula or cleft palate. Initial descriptions identified the syndrome as secondary to mutations in TGF-β receptor 1 *(TGFBR1)* and TGF-β receptor 2 *(TGFBR2)* and were stratified based on severity of craniofacial and cutaneous features. Currently, five variations of LDS have been described. LDS-3 is associated with mutations noted in *SMAD3,* presenting with prominent features of osteoarthritis; LDS-4 and 5 are associated with mutations in *TGFB2* and TGF-β receptor 3 *(TGFB3)*, respectively.[51] Aortic aneurysmal disease is a key feature of LDS. Those with types 1 and 2 with severe craniofacial features are at particularly high risk and have a risk for rupture at smaller diameters with a more malignant presentation. In addition to aortic components, other cardiovascular abnormalities include carotid and vertebral artery tortuosity, aortic stiffness, and mitral annular disjunction. These abnormalities can often present in childhood. Other systemic findings include skeletal involvement (spondylolisthesis and spondylosis), craniofacial abnormalities (abnormal palate, retrognathia, dental malocclusion), neurodevelopmental concerns, and gastrointestinal/genitourinary abnormalities. Multiple recommendations for the management of all of the extraaortic manifestations have been well outlined.[52] Similar to Marfan syndrome, pharmacologic management with either a β-blocker or ARB at maximally tolerated doses is recommended.[3]

Ehlers-Danlos Syndrome

Ehlers-Danlos syndrome (EDS) is a heterogeneous collection of hereditary connective tissue disorders with similar manifestations, including join hypermobility, soft and hyperextensible skin, and abnormal wound healing/easy bruising. There are 14 different types with variants identified in 20 different genes.[53] Overall, EDS has an estimated prevalence of 1:5000 to 1:250,000 births. The main clinical characteristics of EDS are present in varying degrees in each subtype of EDS. A range of clinical manifestations results from the generalized weakness and fragility of the soft connective tissues. Type IV EDS, or the vascular type (vEDS), is an autosomal dominant defect in type III collagen synthesis. These patients are at risk for arterial dissection, rupture, and aneurysm formation. The median life expectancy for patients with vascular EDS is 40 to 50 years. Mutations of the *COL3A1* gene are the predominant etiology of vascular EDS, and individuals with these mutations have structural defects of the pro α1 (III) chain of collagen type III.

Most of the mutations are single base substitutions for glycine residues. Although the vascular presentations can involve the aorta, they more frequently involve the mid- to small-size arteries. They can present with pseudoaneurysm formation, arterial dissection, and spontaneous rupture of nondilated vessels. The mainstay of therapy for patients with vEDS is education and awareness. They should be referred to a center with—and just this connection has been demonstrated to lower mortality rates. Elective interventions should be avoided if possible because of the high-risk nature of any procedure. A targeted approach, either endovascular or open, is warranted in the urgent/emergent scenario.

AORTIC TRAUMA

Both blunt and penetrating trauma may involve any section of the aorta; however, most penetrating injuries to the aorta at any level result in either rapid exsanguination or presentation of a profoundly unstable patient to the emergency department. The most commonly identified treatable aortic injury is blunt disruption of the proximal descending aorta. During a severe trauma with rapid deceleration, shearing and torsion may occur, particularly where the relatively mobile arch transitions to the less mobile descending aorta. This area can sustain a shear injury with varying degrees of injury to the aortic wall. Surprisingly, patients presenting with blunt aortic injury are often hemodynamically stable on presentation because most injuries are either not full-thickness tears or bleeding is contained by the periaortic connective tissue.

The recommended treatment depends on the severity of the injury, which can be graded on a scale of I to IV (Fig. 102.13). Grade I injuries, consisting of intimal tears, can be managed nonoperatively, with serial CT scans to assess for progression or resolution. For grade II, III, and IV injuries, repair with a thoracic endograft (TEVAR) is generally recommended. Although open repair with replacement of the injured segment was considered standard in the past, TEVAR is a much less morbid operation that is more appropriate for polytrauma patients, most of whom have severe associated injuries and are poor candidates for a thoracotomy and an aortic cross clamp. Clinical practice guidelines from the SVS support TEVAR as the preferred modality for treatment of blunt thoracic injury, which has now almost completely replaced open repair.[54]

Timing of repair is frequently a concern because these patients usually have associated orthopedic, neurologic, and abdominal injuries that need to be addressed promptly. Immediate repair within minutes or hours of identification of the aortic injury was originally advocated based on early case series that documented an exceptionally high rate of death within the first few hours of presentation. In this past era, the aortic repair was prioritized over other injuries. More recently, it has been recognized that most blunt aortic injuries identified on CTA have a low risk of rupture in the short term. Addressing head injuries or abdominal trauma before a trip to the OR for aortic repair, which may involve heparinization or hemodynamic instability, has become common practice. The exception would be patients with a grade IV injury, which essentially represents complete transection and may be at high risk for early free rupture (see Fig. 102.13).

A recent study in the *Journal of Vascular Surgery* comparing early (<24 hours) versus late (>24 hours) repair using the National Trauma Data Bank found that the mortality of early repair (9.8%) was significantly higher than that for late repair (4.4%). Although there is potential for significant selection bias because patients with more severe aortic injuries may have been taken more quickly to the OR, this study highlights the relatively low rate of rupture during a 24- to 48-hour period of stabilization before aortic repair.[55] A prudent approach in the current era would involve early repair of grade IV injuries, delaying repair of grade II and III injuries until associated traumatic injuries have been addressed. Patients with less significant blunt aortic injuries who do not have severe associated head or intraabdominal injuries can be repaired immediately as well. For patients with severe head injury, maintaining cerebral perfusion with blood pressure elevation may be a key part of treatment. In this circumstance, early aortic repair should also be considered because medical management of the aortic injury with antiimpulse therapy may be incompatible with treatment goals for a head injury.

Patients with aortic stab or gunshot aortic wounds who survive to definitive repair are rare; however, a partial-thickness injury or a pseudoaneurysm may be contained by the surrounding soft tissues, and the patient may survive to reach a trauma center. Iatrogenic injuries resulting from errant line placement, misadventures during spine surgery, or puncture with trocars during laparoscopic procedures are encountered not infrequently and may result in acute bleeding or a more contained injury identified postoperatively (see Fig. 102.13). For the patient who is unstable with acute

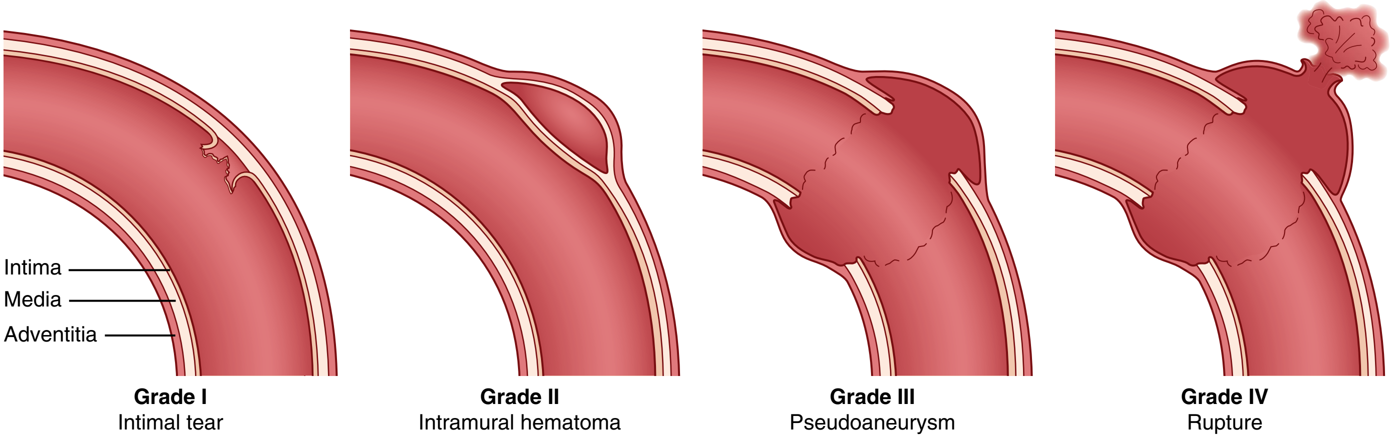

FIGURE 102.13 Classification of blunt thoracic aortic injury.

bleeding, open repair via the most expeditious exposure offers the only possibility of survival.

An underappreciated difficulty with aortic injuries that are explored without the benefit of preoperative imaging is identification of the site and nature of the injury in a field with a large hematoma or active bleeding. For the unstable patient with abdominal injury, a midline laparotomy is almost always employed initially, and central retroperitoneal hematoma, whether stable or expanding, raises the possibility of aortic injury. Dissection of the supraceliac aorta with placement of a clamp before entering a hematoma is a prudent maneuver and can limit both massive blood loss and the associated OR chaos.

Direct suture repair of smaller injuries is sometimes feasible; however, injuries involving more than 50% of the circumference typically require a segmental replacement of the injured aortic segment or placement of a patch to avoid excessive narrowing of the artery. Associated bowel injuries may make contamination of the graft concerning, and off-the-shelf biologic materials such as cryopreserved arterial allograft or bovine pericardium can lessen but not eliminate the risk.

Less morbid endovascular approaches may be considered in patients who are temporarily stable, and stent grafting may be particularly applicable in the descending thoracic aorta or the infrarenal abdominal aorta, where off-the-shelf endografts can be used to rapidly exclude an injured segment. For injuries in proximity to major branches, whether in the arch or the visceral segment, creating an appropriate branched graft in a short time period may be impossible or ill-advised. Some institutions may, however, have the requisite in-house expertise, and back-table modification of grafts has been occasionally employed successfully.

Haulon S, Greenberg RK, Spear R, et al. Global experience with an inner branched arch endograft. *J Thorac Cardiovasc Surg*. 2014;148(4):1709-1716.

This mansucript reports on the initial outcomes of the international use of a branched aortic endograft to treat aortic disease involving the arch. The procedural success was 84% with a 30-day mortality of 13%. Factors, such as early surgical experience and aortic morphology, were determined to be associated with higher rates of early mortality and stroke.

IMPROVE Trial Investigators. Comparative clinical effectiveness and cost effectiveness of endovascular strategy v open repair for ruptured abdominal aortic aneurysm: three year results of the IMPROVE randomised trial. *BMJ*. 2017;359:j4859.

The IMPROVE trial was a randomized trial comparing EVAR and open surgery for ruptured abdominal aortic aneurysms. Results indicated that the EVAR strategy was associated with a 48% mortality rate compared to 56% in the open repair group, alongside improved early quality of life and reduced hospital stays, leading to a gain of 0.17 quality-adjusted life years and lower overall costs, making it a potential cost-effective option.

The 2022 ACC/AHA Guideline provides a comprehensive, evidence based recommendation on the diagnosis and management of aortic disease including medical and surgical management. It offers up to date information on toipcs such as shared-decision making and advances in imaging and genetic testing to individualize treatment option.

Mastracci TM, Eagleton MJ, Kuramochi Y, Bathurst S, Wolski K. Twelve-year results of fenestrated endografts for juxtarenal and group IV thoracoabdominal aneurysms. *J Vasc Surg*. 2015;61(2):355-364.

This study reports one of the longest, single-center outcomes for the use of fenestrated endograft repair of paravisceral aneurysms. Despite being investigational in nature, use of these devices was associated with excellent clinical outcomes. 8-year survival, however, was only 20% with the majority of patients dying from etiology independent of their aortic disease.

Milewicz DM, Guo D, Hostetler E, Marin I, Pinard AC, Cecchi AC. Update on the genetic risk for thoracic aortic aneurysms and acute aortic dissections: implications for clinical care. *J Cardiovasc Surg (Torino)*. 2021;62(3):203-210.

This review highlights the role of genetic variations in predisposing individuals to thoracic aortic aneurysms and dissections. They emphasize that advancements in genomic research have identified 11 genes associated with heritable thoracic aortic disease and the importance of integrating genetic testing in the clinical evaluating and treatment recommendations.

1-year outcome. *J Thorac Cardiovasc Surg*. 2010;140(suppl 6):S101-108; discussion S142-S146.

The INSTEAD trial evaluated 140 patients with stable type B aortic dissection randomized to best medical therapy or endovascular treatment in combination with best medical therapy. At 1-year, despite favorable aortic remodeling in the endovascular arm, no differences in survival or incidence of adverse events was observed.

Nienaber CA, Kische S, Rousseau H, et al. Endovascular repair of type B aortic dissection: long-term results of the randomized investigation of stent grafts in aortic dissection trial. *Circ Cardiovasc Interv*. 2013;6(4):407-416.

This manuscript reports the long-term results of the INSTEAD trial – a randomized, prospective trial evaluating treatment of stable aortic dissections with best medical therapy with and without the addition of TEVAR. The use of TEVAR was associated with favorable aortic remodeling.

Oderich GS, Forbes T, Chaer R, et al. Reporting standards for endovascular aortic repair of aneurysms involving the renal-mesenteric arteries. *J Vasc Surg*. 2021;73(suppl 1):4S-52S.

This represents the reporting standards for evaluating outcomes of patients undergoing endovascular repair of aortic aneurysms that involved the renal and mesenteric arteries. This is the first edition of these recommendations given the relative newness of this treatment modality.

Pape LA, Awais M, Woznicki EM, et al. Presentation, diagnosis, and outcomes of acute aortic dissection: 17-year trends from the international registry of acute aortic dissection. *J Am Coll Cardiol*. 2015;66(4):350-358.

Over a 17-year period, the IRAD study observed consistency over time in the physical complaints expressed by patients having an aortic dissection. The frequency of CT imaging increased during this study, as did the frequency of surgery for type A dissections and endovascular therapy for type B dissections with decreased mortality.

Schermerhorn ML, Buck DB, O'Malley AJ, et al. Long-term outcomes of abdominal aortic aneurysm in the Medicare population. *N Engl J Med*. 2015;373(4):328-338.

This study evaluated the long-term outcomes of EVAR versus upen repair for patients with abdominal aortic aneurysms. The Medicare-based data set demonstrated higher rates of late rupture and need for reintervention for patients that were treated with EVAR, despite an early survival advantage.

  Etiology: Embolism Versus Thrombosis
  Management

INTRODUCTION

Peripheral artery disease (PAD) is an obliterative process that affects extremity arteries and can lead to arterial insufficiency, most commonly in the lower extremities. Although atherosclerosis is the most common etiology of PAD, less common conditions include thromboembolism, vasculitis, thromboangiitis obliterans (Buerger disease), Behcet disease, pseudoxanthoma elasticum, popliteal entrapment syndrome, cystic adventitial disease, and iliac artery endofibrosis. Patients with PAD can present with intermittent claudication (IC), chronic limb-threatening ischemia (CLTI) with symptoms of rest pain or tissue loss (nonhealing ulcers or wounds), and acute limb ischemia (ALI); approximately 30% to 60% of patients with PAD are asymptomatic.[1] The chronic manifestations of atherosclerotic PAD, IC, and CLTI will be discussed in detail because they are most frequently encountered, and the presentation and management of ALI, a surgical emergency, will be described later in the chapter.

Atherosclerosis is a systemic disease, and a substantial number of patients with PAD have concomitant coronary artery disease (CAD) and cerebrovascular disease (CVD). Consequently, patients with PAD have a significantly increased risk of cardiovascular morbidity and mortality. At 32%, 5-year mortality in PAD is higher than that for many cancers.[2] Untreated CLTI, the most severe form of chronic ischemia, carries a 1-year 22% all-cause mortality, and limb loss rates are between 20% and 40%.[3,4] PAD is also associated with impaired quality of life, frailty, and depression.[5–8]

Over the course of the first decade of the 21st century, the prevalence of PAD across the world increased by almost 25%, affecting over 200 million people, with continued growth attributed to the aging population and the epidemic of diabetes mellitus (DM) and metabolic syndrome.[9,10] In addition, chronic kidney disease (CKD) and hypertension (HTN) are contributing to the development and progression of PAD globally. The true prevalence of PAD is likely underestimated as a result of underdiagnosis and the presence of asymptomatic disease. Data and models from the Global Burden of Diseases, Injuries, and Risk Factors Study demonstrated a 75% increase in mortality and a 37% increase in disability associated with PAD, in contrast to the decreasing prevalence and disease-related mortality of ischemic heart disease and ischemic stroke over the same time period.[11]

In the United States, PAD affects an estimated 8.5 to 12 million people and is associated with high economic burden.[12] In an analysis of the Agency for Healthcare Research and Quality Medical Expenditure Panel Surveys from 2011–14, reported annual expenditures per individual with PAD were $11,553 compared with just $4219 for matched patients without PAD.[13] Comorbid conditions associated with PAD also contribute to the economic cost. For patients with DM and PAD, total costs were significantly higher as compared with patients with DM alone ($33,894 vs. $12,151).[13] Approximately one-third of the $237 billion in direct costs of care for diabetic patients in 2017 was attributed to the care of diabetic foot disease, which is comparable to cancer-related expenditures.[14] Additionally, smoking has been shown to be associated with a 35% higher annual hospitalization rate and $18,000 higher annual cost per patient with atherosclerotic PAD.[15]

PATHOPHYSIOLOGY OF ATHEROSCLEROTIC DISEASE

Arteries consist of three layers: intima, media, and adventitia. The innermost intima, composed of collagen and glycosaminoglycans, is largely acellular and is lined with endothelium, a cell monolayer in contact with the bloodstream. The media consists of layers of smooth muscle cells and is surrounded by adventitia, the fibrous outer layer, which provides strength to the vessel wall.

Atherosclerosis is a dynamic process and is believed to be the result of chronic inflammation of the arterial wall.[16] When the endothelium is activated by proinflammatory stimuli, endothelial cells express leukocyte adhesion molecules to which circulating blood monocytes and lymphocytes adhere. These bound leukocytes migrate into the intima, where they differentiate into macrophages. Foam cells form when macrophages take up lipoproteins, leading to the development of fatty streaks within the luminal surface of the arteries.

Vascular smooth muscle cells proliferate and migrate to the subendothelial space of the intima, forming a fibrous cap through the secretion of extracellular matrix material, primarily collagen (Fig. 103.1). Over time, as foam cells, smooth muscle cells, and macrophages continue to accumulate, cells undergo apoptosis, leading to the appearance of a necrotic core consisting of cholesterol and cellular debris within the plaque. Episodes of systemic or regional inflammation stimulate lesion growth through T-cell lymphocyte-mediated interactions, resulting in expansion of the necrotic core and thinning of the fibrous cap, making the plaque susceptible to disruption. Plaque rupture or superficial erosion of the endothelial lining exposes the thrombogenic substances contained within the necrotic core, including tissue factor, to circulating blood components, triggering coagulation and thrombosis.[17]

Calcifications are common in atherosclerotic lesions and increase with advancing age as well as in patients with DM and CKD. Apoptotic cells, necrotic core, and extracellular matrix can act as a nidus for deposition of microscopic calcium granules, which can progress to larger deposits and complete calcification of the necrotic core.[18]

Arteries demonstrate compensatory changes in response to development of atherosclerotic plaques. Arterial remodeling occurs in two stages: compensation and encroachment.[19] As atherosclerotic plaques enlarge, arterial enlargement results in preservation of luminal diameter until the lesion occupies ~40% of the cross-sectional area, at which point encroachment occurs and the lumen becomes progressively narrowed, limiting blood flow to distal tissues.

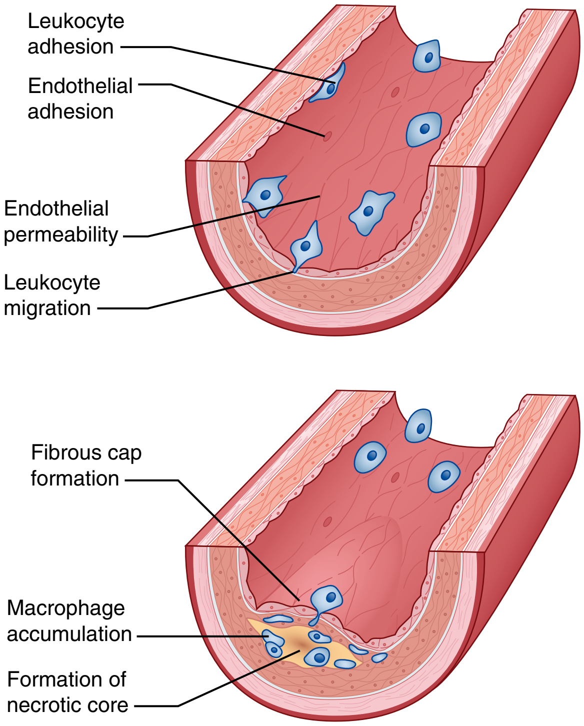

FIGURE 103.1 Initiation and progression of atherosclerotic plaque. Cardiovascular risk factors, hemodynamic forces, toxins, and infectious agents interact with the vessel at the level of the endothelium to produce injury, resulting in decreased nitric oxide production and increased permeability. Once injured, the endothelium increases the expression of leukocyte adhesion molecules such as vascular cell adhesion molecule-1, intracellular adhesion molecule-1, and P- and E-selectin, which increases the adherence of macrophages and other leukocytes. Permeability of the endothelium also increases and permits entry of leukocytes and lipoproteins into the subendothelial space. Chemokines and cytokines such as monocyte chemotactic protein-1 and interleukin-8 further enhance the recruitment of leukocytes and smooth muscle cells (SMCs) into the subendothelial space. Lipoproteins retained in the subendothelial space are biochemically modified such that they can be taken up by macrophages and SMCs to form foam cells. Foam cells at the central-most position of the developing atheroma become necrotic and form the central lipid core, whereas the shoulder regions contain SMCs, macrophages, and other leukocytes. Platelet-derived growth factor and transforming growth factor-β stimulate SMC migration and collagen formation in the subendothelial space as well as formation of the fibrous cap. (Ho KJ. Atherosclerosis. In: Sidawy AN, Perler BA, eds. *Rutherford's Vascular Surgery and Endovascular Therapy.* 10th ed. Philadelphia: Elsevier; 2019:41-50.)

ANATOMIC PATTERNS OF ATHEROSCLEROTIC DISEASE

In the extremity, atherosclerotic plaque develops in relatively predictable distributions (Fig. 103.2). Lesions tend to occur at arterial bifurcations, areas of fixation and angulation. The most common location is the distal superficial artery (SFA) at the adductor hiatus. In this location, the artery is compressed by the adductor magnus tendon, which causes trauma to the artery and limits its ability to develop compensatory arterial dilation.

Flow separation and turbulence lead to areas of shear stress, predisposing the vessel to vascular injury and atherogenesis. Although asymmetrical intimal thickening may initially form as an adaptive physiologic response, it represents a vulnerable location for the development of pathologic atherosclerotic lesions.[20] Plaque accumulation leads to formation of stenoses that further disrupt laminar flow, causing eddy currents that continue to traumatize the intima, leading to vessel stenosis and occlusion.

In response to arterial stenosis, collateral vessels develop from distributing branches of large and medium-sized arteries. These collaterals may provide sufficient flow to the limb despite the presence of severe arterial stenosis or occlusion. If collateral formation keeps pace with disease progression, the patient may either remain asymptomatic or have stable symptoms. However, when aggressive native arterial disease progresses faster than collateral formation or interrupts flow to collateral vessels, or if collateral flow is reduced in the setting of decreased cardiac output or increased blood viscosity, then PAD symptoms can worsen.

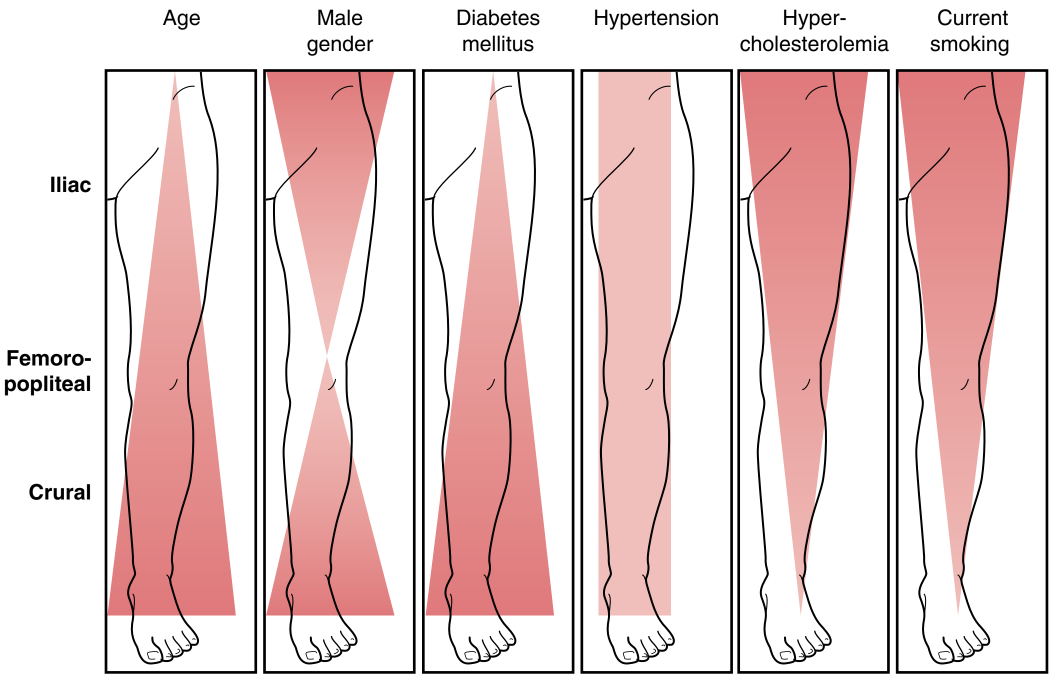

FIGURE 103.2 Association of risk factors with the level of atherosclerotic target lesions. The *red* overlay on the anatomic cartoon illustrates the association of risk factors with patterns of atherosclerotic disease. (From Diehm N, Shang A, Silvestro A, et al. Association of cardiovascular risk factors with pattern of lower limb atherosclerosis in 2659 patients undergoing angioplasty. *Eur J Vasc Endovasc Surg*. 2006;31:59-63.)

Patients with IC often have single-level disease, commonly involving either the aortoiliac segment or femoropopliteal segment. The former is a pattern commonly seen in cigarette smokers. Patients with CLTI frequently have multilevel disease, with more than half demonstrating not only occlusions in the femoral but also the popliteal and/or tibial arteries.[21] Female sex, especially in current and prior smokers, and patients with elevated triglycerides have been found to have an association with aortoiliac disease.[22] Females with CLTI have also been demonstrated to have a higher risk of occlusions and multilevel disease.[23]

DM, CKD, and older age are associated with the development of more distal disease. Patients with DM frequently present with severe occlusive disease involving long-segment occlusions of the tibial arteries as well as more frequent involvement of the deep femoral artery (DFA). The anterior tibial (ATA) and posterior tibial (PTA) arteries are the most frequently involved, with the peroneal artery least affected.[24] Despite the predilection for a distal distribution of disease in patients with DM, the pedal arteries are often spared. A study of arteriographic lesions in diabetic patients with ischemic foot ulcers demonstrated that 88% of patients with occlusion of all tibial vessels had at least one patent pedal artery.[25]

Patients with end-stage renal disease (ESRD) have more frequent involvement of the pedal vessels.[26] Renal insufficiency is associated with arterial calcification, and CKD has also been shown to be associated with a loss of patency of the pedal-plantar arch.[27]

Patterns of disease have implications for revascularization options. In particular, management of distal disease is more challenging, often placing patients at higher risk of amputation and limited amputation-free survival.[28]

EPIDEMIOLOGY AND RISK FACTORS

Advanced age, DM, CKD, cigarette smoking, HTN, and hyperlipidemia increase the risk of PAD. PAD most commonly presents in patients older than 50 years of age, and prevalence increases with increasing age. Among patients younger than 50 years, PAD prevalence is 4% to 7%, compared with 15% to 20% in patients older than 80 years.[9,29] This represents a significant risk factor because by 2030, US Census data project that 19.3% of the population will be over 65 years of age.[30]

DM, affecting over half a billion people globally, is associated with both microvascular and macrovascular complications and has become the most quickly increasing risk factor for PAD. By 2050, 50% of the global adult population is expected to have DM, which is associated with a two- to fourfold increase in PAD prevalence.[31–33] Risk increases with worsening glycemic control, with each 1% increase in HbA1c from baseline associated with a 14.2% increased relative risk (RR) of major adverse cardiovascular events (MACEs)[34] and a 21% to 28% increased risk of PAD.[35,36] Of patients with CLTI, 60% to 70% of patients have a diagnosis of DM.[21] Up to one-third of patients with DM will develop a diabetic foot ulcer (DFU) during their lifetime, which can be purely neurogenic, although many are neuro-ischemic.[14] Patients with DM and PAD have a four-times-higher risk of major limb amputation,[37] and elevated serum fasting glucose is the primary attributable risk factor for PAD-related mortality, surpassing risk factors of smoking and HTN in the overall population.[38]

CKD has also emerged as a significant independent risk factor for the development of PAD. Prevalence of PAD is 25.2% among patients with renal insufficiency, and approximately 25% of patients undergoing revascularization for PAD have CKD.[39,40] Patients with CKD and PAD who undergo revascularization experience worse outcomes, including increased risk of leg amputation and death.[40] CKD is the predominant contributor to PAD-related mortality in patients 40 to 59 years old, especially females.[38]

Smoking, a major modifiable risk factor, has a three- to fourfold increased risk for the development of PAD.[41] The Reduction of Atherothrombosis for Continued Health (REACH) Registry data indicate that 22% of patients with clinically evident PAD continue to use tobacco.[42] Cigarette smoking induces endothelial dysfunction, oxidative stress, and production of inflammatory and proatherogenic cytokines and induces a prothrombotic state with platelet aggregation and vasoconstriction.[41] The Atherosclerosis Risk in Communities (ARIC) study demonstrated the dose-response relationship between pack-years of smoking and incidence of PAD, CAD, and stroke as well as the elevated risk of PAD, which persists even after 30 years of smoking cessation.[43] Smokers have a threefold risk of bypass graft failure, with a clear dose-response relationship with smoking intensity.[44] Smoking is associated with increased mortality and decreased amputation-free survival. In patients with claudication or CLTI, 5-year mortality was lower in patients who successfully quit smoking than those who continued to smoke (14% vs. 31%), and the benefit was more notable in the CLTI cohort (18% vs. 43%).[45] Additionally, amputation-free survival was improved in the successful smoking cessation group (hazard ratio [HR] 0.43, 95% CI 0.22–0.86).[45]

HTN increases the odds of developing PAD by 1.32 to 2.20 times.[29] Given the high prevalence of HTN in the older population, this represents a large contribution to the burden of PAD. The ARIC study found a graded association of systolic blood pressure (SBP) with PAD, reporting an adjusted HR of 2.6 for SBP of ≥140 mm Hg and 1.6 for 120 to 139 mm Hg.[46]

Although total cholesterol and low-density lipoprotein cholesterol (LDL-C) have been shown to be independently associated with coronary heart disease, the associations with PAD have not been found to be significant.[47] However, higher baseline levels of triglyceride-related lipids and lower levels of high-density lipoprotein (HDL)-related lipids were independently associated with incident PAD in the ARIC study.[48] In a case-control study of 14,916 male physicians that examined lipid biomarkers, the ratio of total cholesterol to HDL-C was the strongest predictor of risk for PAD (RR 3.9; 95% CI 1.7–8.6).[49]

Differences in the prevalence, management, and outcomes for PAD differ between the sexes. The cross-sectional part of the German Epidemiological Trial on Ankle Brachial Index (getABI) study examined the ABIs of over 6000 consecutive, unselected patients and found that before age 70, males have a higher prevalence of PAD than females (17% vs. 12%), but prevalence was higher in females in the population older than 85 years (39% vs. 27%).[50] Although there is an increased prevalence in males from high-income countries, females from lower-income countries experience PAD at up to two times the rate of males.[12] Females are at increased risk of asymptomatic PAD, are less likely to be prescribed optimal medical therapy, and are more likely to present with more severe disease.[51] Additionally, females have an increased incidence of postprocedural complications, including access site complications, pedal access failures, surgical bleeding, wound complications, and perioperative infections.[52,53]

Studies have sought to define the association of race and ethnicity with risk of PAD and outcomes. A review of studies from 1999–2022 found that Black patients with PAD and DM had an increased risk of amputation and underwent fewer revascularization procedures than White patients.[54] Black race was found to be an independent risk factor for major amputation when controlling for comorbid conditions, PAD severity, and medication use as compared with White patients from similar socioeconomic strata.[55] Even with successful revascularization, Black patients with CLTI are 1.5 to 2 times more likely to require a major amputation.[56] Hispanic patients with CLTI also have worse outcomes when compared with non-Hispanic White patients. In a study of Hispanic patients hospitalized for lower extremity PAD, Hispanic patients were noted to have a higher burden of comorbid conditions, including DM, ESRD, and previous amputations; presented with more severe PAD; had lower rates of revascularization; and had higher rates of amputations.[57]

Socioeconomic status has been identified as an important determinant of health and outcomes in PAD patients. Patients with lower socioeconomic status have been shown to be at increased risk for the development of PAD, attributed to the increased prevalence of PAD risk factors in this population, decreased access to care, and underutilization of secondary prevention measures, leading to increased rates of amputation and decreased postoperative survival.[58] In patients undergoing infrainguinal revascularization for PAD, patients from more disadvantaged neighborhoods, as defined by the area deprivation index (ADI), a measure created by the Health Resources and Services Administration using census data, presented with more advanced disease and underwent lower rates of revascularization.[59] Among 958,120 CLTI patients in the Nationwide Inpatient Sample, PAD patients in the lowest income quartile had 34% higher odds of undergoing amputation as compared with patients in the highest income quartile.[60]

Other risk factors for PAD include hypertriglyceridemia, elevated serum fibrinogen, and hyperhomocysteinemia. Nonconventional risk factors also linked to be linked to PAD include elevated inflammatory markers, human immunodeficiency virus, exposure to lead and cadmium, and depression.

CLINICAL PRESENTATION OF PERIPHERAL ARTERY DISEASE

PAD can result in a range of clinical presentations, the severity of which can be assessed with a detailed history and physical examination. History should include location and duration of symptoms, progression of symptoms over time, walking impairment and associated disability, modifying factors, skin changes, and slow-to-heal wounds. Past medical history should assess risk factors for development of PAD, including tobacco use, HTN, hyperlipidemia, DM, history of CAD, CKD, prior revascularizations, personal or family history of aneurysmal disease, embolic events, or hypercoagulable states.

IC describes cramping or aching pain in the muscles of the leg that occurs with activity but is not present at rest. This is a result of the increased oxygen demand of the muscles while walking, which cannot be met because of the presence of upstream arterial stenoses or occlusions. Claudication symptoms are often reliably reproducible, with patients often able to specify the exact distance at which symptoms arise. Symptoms may occur more quickly by walking uphill or at a faster pace and typically resolve with a short period of rest. One muscle group distal to the area of arterial disease is usually affected, with aortoiliac pathology causing symptoms in the buttocks and thighs, whereas femoral-popliteal disease results in calf claudication. Leriche syndrome describes the triad of IC, absent femoral pulses, and impotence secondary to aortoiliac occlusive disease (AIOD).[61]

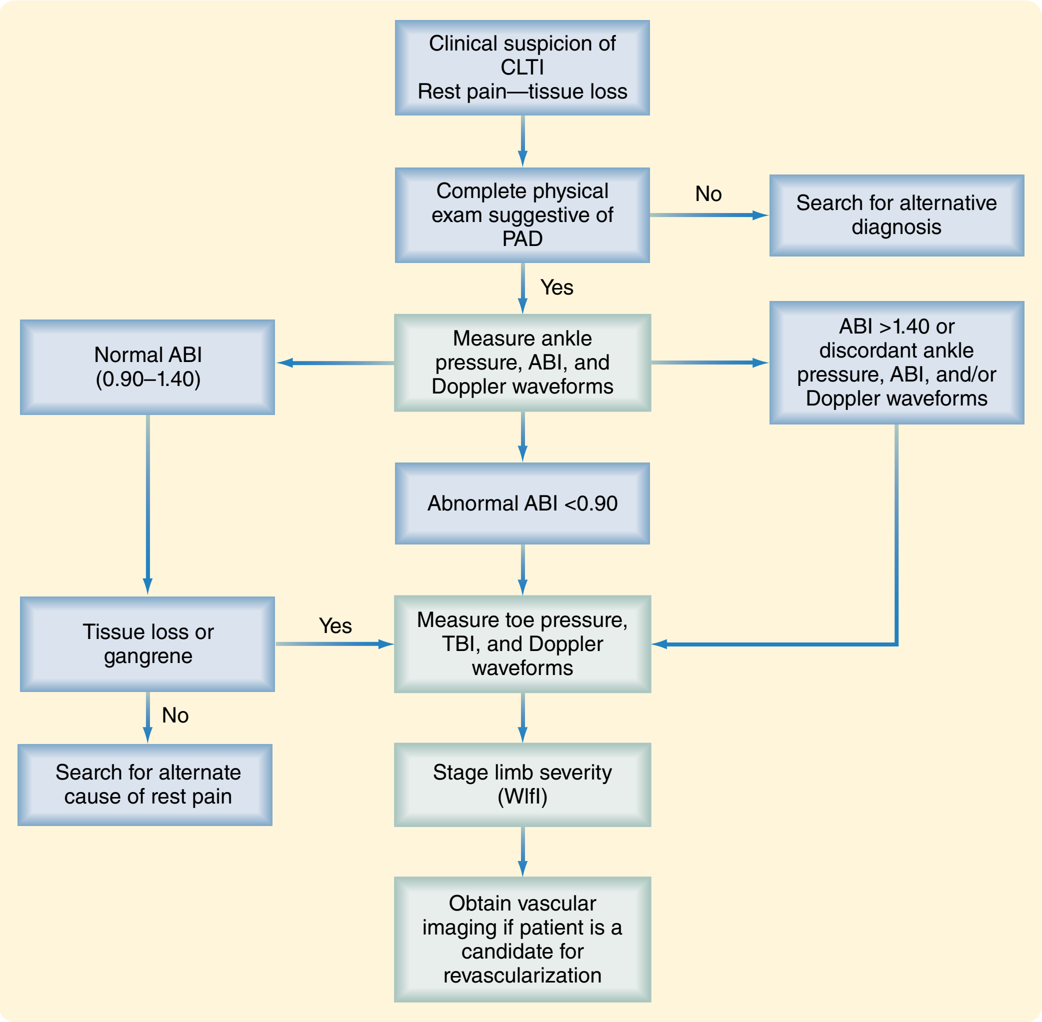
Vasculogenic claudication must be differentiated from other conditions that can induce leg pain with exertion, including spinal stenosis, nerve root compression, arthritis, and chronic compartment syndrome. Although vascular and neurologic etiologies of leg pain can coexist, neurogenic conditions are often more variable in onset and may take longer to resolve; symptoms may arise from standing alone and can often be relieved by changes in position.

Ischemic rest pain and tissue loss are symptoms of advanced PAD, termed *CLTI*. Rest pain occurs in the forefoot, typically worsens with leg elevation, and improves when the limb is in a dependent position. Patients may report that they sleep with the affected extremity dangling off the bed because the increase in pedal blood pressure secondary to gravity may provide sufficient pain relief. Ischemic rest pain is more commonly observed in smokers, likely as a result of the coexistent peripheral sensory neuropathy that may mask symptoms in diabetics. Diabetic neuropathy, gout, and degenerative joint disease may also cause symptoms similar to rest pain. In CLTI, tissue loss involves ulceration or gangrene of the lower leg or foot present for more than 2 weeks in duration and occurs along with objective evidence of arterial insufficiency severe enough to impede wound healing.

Observation of the extremities should note temperature changes, absence of hair growth and dry skin caused by apocrine gland dysfunction, signs of muscle atrophy, changes in color, dependent rubor, elevation pallor, and presence of ulcerations or gangrene. Peripheral pulses (carotid, brachial, radial, ulnar, femoral, popliteal, dorsalis pedis [DP], PT) should be palpated. Nonpalpable pulses, as well as prominent pulses in the abdomen, femoral, and popliteal regions, which may suggest presence of an aneurysm, should be noted. The neck, abdomen, and groin should be auscultated for bruits. Loss of protective sensation in patients with neuropathy should be assessed with Semmes-Weinstein monofilament test, and the probe-to-bone test should be performed in patients with ulcers.[62]

DIAGNOSTIC MODALITIES IN PERIPHERAL ARTERY DISEASE

In patients suspected to have PAD, lower extremity noninvasive studies performed in a vascular laboratory can confirm the diagnosis and guide further workup and treatment (Figs. 103.3 and 103.4). These include the ankle-brachial index (ABI), segmental pressures, toe pressures, pulse volume recordings (PVRs), and tibial Doppler waveforms. Transcutaneous oximetry ($TcPO_2$) is used to determine whether blood flow to the area of interest is sufficient for healing to take place. These noninvasive studies can assist in quantifying the degree of arterial insufficiency and localize the level of stenoses or occlusions.[63] Imaging studies such as arterial duplex, computed tomography angiography (CTA),



Clinical suspicion of CLTI Rest pain—tissue loss
Complete physical exam suggestive of PAD
No
Search for alternative diagnosis
Yes
Normal ABI (0.90–1.40)
Measure ankle pressure, ABI, and Doppler waveforms
ABI >1.40 or discordant ankle pressure, ABI, and/or Doppler waveforms
Abnormal ABI <0.90
Tissue loss or gangrene
Yes
Measure toe pressure, TBI, and Doppler waveforms
No
Search for alternate cause of rest pain
Stage limb severity (WIfI)
Obtain vascular imaging if patient is a candidate for revascularization

Define preferred target arterial pathway

FIGURE 103.4 Suggested algorithm for anatomic imaging in patients with chronic limb-threatening ischemia who are candidates for revascularization. In some cases, it may be appropriate to proceed directly to angiographic imaging (computed tomography angiography *[CTA]*, magnetic resonance angiography *[MRA]*, or catheter) rather than to duplex ultrasound imaging. (From Conte MS, Bradbury AW, Kolh P, et al. Global vascular guidelines on the management of chronic limb-threatening ischemia. *J Vasc Surg.* 2019;69:3S-125S.e40.)

magnetic resonance angiography (MRA), and digital subtraction angiography (DSA) are used to further define the arterial anatomy in patients considered for possible intervention.

Noninvasive Vascular Studies

Ankle Pressure and Ankle-Brachial Index

Measurement of systolic ankle pressures is used to assess the degree of distal ischemia, and these are measured using a handheld Doppler and blood pressure cuff. Incorporation of the ankle pressures in the ABI provides an objective measure of the severity of PAD and is useful for longitudinal surveillance of disease progression. The ABI is defined as the ratio of the highest systolic ankle pressure (DP or PTA) to the highest systolic brachial pressure in millimeters of mercury (mm Hg). The normal range is 0.9 to 1.2. An ABI of <0.9 has a sensitivity of 79% to 95% and a specificity of $>95\%$ in establishing the diagnosis of PAD.[64] Ankle pressures <70 mm Hg in the setting of tissue loss and pressures <50 mm Hg for ischemic rest pain, as well as an ABI <0.5, are consistent with a diagnosis of CLTI.[65]

In patients with symptoms consistent with IC and normal or borderline ABI, an exercise ABI can be performed. After baseline ABIs are recorded, the patient walks on a treadmill at an incline for 5 minutes or until limited by pain, and immediately after finishing this activity, the ABI is measured. During exercise, peripheral vascular resistance decreases, allowing increased blood flow to the muscles. In the setting of stenosis, the differential in blood pressures before and after the lesion becomes more pronounced. A positive test is defined by a decrease in ankle pressure of ≥ 20 mm Hg, $\geq 20\%$ decrease from baseline, decrease of ABI of ≥ 0.2, or failure of ABI to return to baseline within 3 minutes.

Toe Pressure and Toe-Brachial Index

The increased vascular calcifications observed in patients of advanced age, CKD, and DM result in stiff, noncompressible vessels and falsely normal or elevated ABIs (>1.3), which have been shown to be associated with a greater likelihood of amputation and worse amputation-free survival.[66] In these patients, toe pressure and toe-brachial indices can be a better measure of distal ischemia because toe vessels are less often affected by calcification. A toe-brachial index ≤ 0.75 is abnormal and indicates the presence of hemodynamically significant PAD. An absolute toe pressure <30 mm Hg indicates severe arterial insufficiency that would make wound healing unlikely without revascularization.[67] A toe pressure >60 mm Hg is associated with a significant likelihood of healing.

Segmental Pressures

Multiple pneumatic cuffs are placed on each extremity (high thigh, above knee, below knee, and proximal to the ankle), and the arterial pressure at each level is measured using continuous-wave Doppler at the DP as the cuff is deflated. The location of occlusive lesions can be estimated by comparison of the pressures, with a drop in pressure of ≥20 mm Hg between any two levels considered to be hemodynamically significant.

Pulse Volume Recordings

PVR waveforms are obtained using partially inflated air-filled cuffs that detect changes in volume in the limb transmitted from the arterial pulse wave. Normal waveforms have a sharp systolic upstroke, narrow peak, and downstroke toward baseline, with a prominent dicrotic notch. Occlusive disease results in delay of the systolic upstroke, rounded peak, and loss of the dicrotic notch, whereas more severe disease leads to decreases in amplitude or absent waveforms.[68] Flat or minimally pulsatile PVRs in forefoot are associated with CLTI.[69] The combination of segmental limb pressures and PVRs is reported to have a diagnostic accuracy of 97% in patients suspected to have PAD.[64]

Doppler Waveforms

The arterial waveform can also provide information on the extent of disease. Doppler waveforms are measured at the anterior tibial (AT) and posterior tibial (PT) locations with a continuous Doppler probe. The normal spectral waveform is triphasic, with a sharp systolic upstroke and early diastolic flow reversal, and has a late diastolic return to antegrade flow. Arterial atherosclerosis leads to loss of vascular elasticity, and this results in a loss of phasicity. Multiphasic waveforms in which the waveform crosses the zero-flow baseline and has forward and reverse velocity components become monophasic, and the waveform does not cross the baseline during any part of the cardiac cycle. In the extremity, biphasic and triphasic waveforms are considered normal. Monophasic waveforms are indicative of at least a moderate degree of ischemia.[65]

Transcutaneous Partial Pressure of Oxygen

$TcPO_2$ is a metabolic test that can help to assess local tissue perfusion and estimate chance of potential healing. Skin sensors are applied to selected areas, and the oxygen diffuses from the capillaries through the epidermis to the electrode. A normal $TcPO_2$ is around 60 mm Hg; however, numerous factors can affect the accuracy of measurements, including temperature, skin condition, circulatory status, location of the sensors, patient positioning, and causes of vasoconstriction (e.g., caffeine, smoking, pain, or anxiety).[70] For the test to be interpretable, a control baseline value measured at the chest needs to be >60 mm Hg. Although there is no consensus as to $TcPO_2$ cutoff value to guarantee amputation healing, $TcPO_2$ <30 mm Hg has been associated with failure of healing.[70] $TcPO_2$ ≥40 mm Hg in patients undergoing below-the-knee amputation (BKA) was associated with lower 1-year freedom from conversion to AKA.[71]

Imaging

Arterial Duplex

Arterial duplex is widely available, is noninvasive, and can be used to define the arterial anatomy and estimate the degree of stenoses by using both brightness mode (B-mode) and Doppler ultrasound. B-mode is gray-scale ultrasound that is used to localize and characterize plaque as well as measure vessel diameters. The velocity of blood flow is estimated using Doppler, or pulsed-wave ultrasound. Between two points in a nondiseased artery, the blood flow should be equal. As the cross-sectional area of the vessel decreases as a result of stenoses, the velocity increases proportionally to maintain flow. This luminal narrowing results in an increased peak systolic velocity (PSV) as compared with the normal adjacent proximal segment. The ratio of increase in the PSV corresponds to the degree of stenosis: In <50% stenosis, the PSV is elevated but less than double the normal adjacent proximal segment (ratio <2); a PSV velocity ratio >2 indicates a 50% to 74% stenosis; and a >75% stenosis will display a fourfold increase in PSV.[72]

Additionally, spectral broadening is observed in diseased arteries as a result of the presence of turbulent, nonlaminar blood flow. Duplex is used to plan interventions for symptomatic PAD and is also used as part of regular surveillance after revascularization to monitor development and progression of stenosis.

Computed Tomography Angiography and Magnetic Resonance Angiography

CTA and MRA represent cross-sectional imaging that may be considered when planning intervention, especially when aortoiliac disease is suspected, as in a patient with an absent femoral pulse. The utility of CTA is limited when imaging smaller, distal, calcified lower extremity vessels frequently found in patients with CLTI because calcification impairs definitive lesion characterization as a result of artifact. However, advances in imaging technology, such as the use of dual-energy CTA with postprocessing bone removal protocols[73,74] and use of ultra-high-resolution CT with subtraction techniques,[75] are improving the assessment of stenosis in PAD patients.

MRA avoids exposure to ionizing radiation but requires longer acquisition times. In a meta-analysis comparing contrast-enhanced MRA, duplex sonography, and CTA, MRA was the most accurate diagnostic technique for the detection of lesions with >50% stenosis.[76] The ability of MRA to image blood flow as slow as 2 cm/s improves the diagnostic quality in imaging the infrapopliteal vessels as well as in identifying potential bypass targets not visualized by DSA in diabetic patients.[77,78] Novel magnetic resonance imaging techniques are also emerging that allow for assessment of plaque composition and assessment of skeletal muscle perfusion as well as methods that do not require the use of contrast media.[79]

Digital Subtraction Angiography

DSA is a fluoroscopic technique used to visualize the arterial anatomy using intraarterial injection of contrast dye and x-rays, where the images acquired after contrast injection are subtracted from the images acquired before injection. Angiography is an invasive procedure that carries risk of complications; however, it has the advantage of the ability to perform concurrent therapeutic endovascular interventions at the time of image acquisition. Intravascular ultrasound (IVUS) can also be used as an adjunct during angiography to measure arterial dimensions to help size angioplasty balloons and stents as well as to assess results after intervention.

NONINTERVENTIONAL MANAGEMENT OF PERIPHERAL ARTERIAL DISEASE

The noninterventional management of PAD is critically important. Aggressive treatment of cardiovascular comorbidities prevents progressively worsening atherosclerosis and reduces MACEs, a composite end point of nonfatal stroke, nonfatal myocardial infarction (MI), and cardiovascular death. Furthermore, patients who are medically optimized have better surgical outcomes when patients require revascularization. After revascularization, there are also specific antithrombotic therapies that reduce major adverse limb events (MALEs), including reinterventions and amputations. In addition to optimal medical management, risk factor modification also includes smoking cessation and exercise therapy.

Antithrombotic Therapy

In the PAD population, multiple randomized controlled trials (RCTs) have demonstrated the benefit of single-antiplatelet therapy for secondary prevention to reduce the risk of MI, stroke, and death.[80,81] In asymptomatic PAD patients, there are conflicting data regarding the use of antiplatelet agents for primary prevention in the absence of CAD or CVD.[82] However, given the high proportion of patients with PAD and subclinical CAD, single-antiplatelet therapy may be a reasonable treatment in asymptomatic patients with reduced ABI and low bleeding risk.[83] Additionally, the patients with PAD and concomitant CAD have higher composite rates of MACE (15.3% vs. 8.9%, HR 1.50, 95% CI 1.13–1.99, $p = 0.005$),[84] and patients with a prior MI and PAD have double the cardiovascular risk than those with PAD alone (8.4% vs. 19.3%, $p < 0.001$), highlighting the importance of cardiovascular risk mitigation.[83,85]

Confusion arose in 2022 when the US Preventive Services Task Force (USPSTF) issued new guidance regarding the use of aspirin for primary prevention of MACE in the general adult population, reporting only a small net benefit of acetylsalicylic acid (ASA) in patients 40 to 59 years with a ≥10% 10-year risk of cardiovascular disease and recommending against initiation of ASA in patients ≥60 years.[86] Patients with PAD do not have the same risk profile as the general adult population, and expert consensus is that all patients diagnosed with PAD, who do not have a contraindication, should be prescribed antithrombotic medication. In general, the more significant the burden of atherosclerotic polyvascular disease, the more intensive the antithrombotic treatment strategy.

Although aspirin, a cyclooxygenase 1 inhibitor, is the most frequently used antiplatelet agent, alternative antiplatelet agents such as the P2Y12 receptor antagonists, clopidogrel and ticagrelor, have demonstrated benefit in certain groups. The Clopidogrel Versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) trial of patients with stable atherosclerotic cardiovascular disease found that in the subset of patients with symptomatic PAD, clopidogrel was associated with fewer cardiovascular events (3.71% average event rate per year in the clopidogrel group vs. 4.86% in the aspirin group).[87] Therefore, in patients with symptomatic PAD, treatment with a single antiplatelet agent, aspirin (75–325 mg/day) or clopidogrel (75 mg/day), is recommended to reduce MACE.[63] Clopidogrel may be the preferred agent in current smokers with PAD because it has been associated with a greater reduction of events than aspirin in patients treated with a single antiplatelet agent.[88] In the Examining Use of Ticagrelor in Peripheral Artery Disease (EUCLID) trial, ticagrelor demonstrated similar benefit to clopidogrel monotherapy in preventing MACE in symptomatic PAD patients (HR 1.02, 95% CI 0.92–1.13, $p = 0.65$), which may highlight a role for ticagrelor in poor clopidogrel metabolizers.[34,84]

Dual-antiplatelet therapy (DAPT) using aspirin in combination with a P2Y12 receptor antagonist has also been investigated. DAPT using clopidogrel plus aspirin in the Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization Management and Avoidance (CHARISMA) trial was not significantly more effective than aspirin alone in reducing MACE in PAD patients and was associated with increased bleeding risk.[89] However, among PAD patients with a history of prior MI, the addition of ticagrelor to low-dose aspirin reduced MACEs and MALEs in the PEGASUS-TIMI 54 study.[90] The extrapolation of data from coronary literature and the use of DAPT in device trials has led to the use of DAPT after peripheral interventions; however, clear data to support its use are lacking.[91]

Low-dose oral anticoagulants have shown benefit in patients with PAD. The subset of 6391 participants with lower extremity PAD included in the Cardiovascular Outcomes for People Using Anticoagulation Strategies (COMPASS) trial demonstrated that rivaroxaban 2.5 mg twice daily plus ASA compared with ASA alone reduced the risk of MACE (5.1% vs. 6.9%, $p = 0.005$) and MALE (1.5% vs. 2.6%, HR 0.57, 95% CI 0.37–0.88).[92] The Vascular Outcomes Study of ASA Along with Rivaroxaban in Endovascular of Surgical Limb Revascularization for PAD (VOYAGER-PAD) randomized 6564 patients undergoing infrainguinal endovascular or surgical revascularization to aspirin and rivaroxaban 2.5 mg twice daily or aspirin and placebo. The rivaroxaban and aspirin group significantly reduced the primary composite end point of ALI, major amputation, MI, ischemic stroke, or cardiovascular death (HR 0.85, 95% CI 0.76–0.96, $p = 0.009$), irrespective of revascularization strategy.[93] A meta-analysis of the PAD patients in the COMPASS and VOYAGER trials concluded that low-dose rivaroxaban plus aspirin was superior to aspirin alone in reducing cardiovascular and limb outcomes, including ALI and major amputation.[94]

When prescribing anticoagulants, even at low doses, potential benefit must be balanced with bleeding risk. Although major bleeding was increased in patients treated with rivaroxaban in both the COMPASS and VOYAGER-PAD trials, fatal or critical organ bleeding was not significantly different.[93,95] In patients without elevated bleeding risk, dual therapy with aspirin and low-dose rivaroxaban is reasonable, but the bleeding risk associated with full-dose anticoagulation outweighs any benefit in reducing adverse cardiac or limb events, and its routine use is recommended against.[63]

Glycemic Control

DM is a significant risk factor for the development and progression of atherosclerosis and PAD, with the severity of disease correlated to long-term glucose control. Regardless of how blood glucose is controlled, having a robust strategy in place to stabilize and control DM improves short-term revascularization outcomes and reduces MALE.[96,97] Tight glucose control has been shown to decrease microvascular complications in the short term and can reduce macrovascular complications, such as cardiovascular outcomes, when maintained over decades.[98,99] Newer studies have shown benefit of sodium-glucose transporter-2 inhibitor (SGLT2i) and glucagon-like peptide (GLP)-1 receptor agonists in reducing cardiovascular mortality, heart failure, renal complications, MACE, and amputation.[100]

A target HbA1c of <7% is recommended by Global Vascular Guidelines for CLTI[69]; however, the International Working Group on the Diabetic Foot (IWGDF) guidelines suggest a higher target HbA1c of <8% because of the risk of hypoglycemia with tighter glucose control.[66] This highlights the need for glucose targets to be individualized based on age, duration of DM, complications, comorbid conditions, and hypoglycemia risk.[66]

Lipid-Lowering Therapy

Statins have been demonstrated to reduce mortality, major adverse cardiovascular outcomes, and MALEs and improve symptomatic outcomes in patients with PAD.[101] Additionally, statins have pleiotropic effects, including improved endothelial function, inhibition of smooth muscle proliferation, plaque stabilization, and reduced platelet aggregation.[102] Therapy with a high-intensity statin, simvastatin 80 mg/day, or rosuvastatin 40 mg/day to achieve an LDL goal of <70 mg/dL is recommended in all patients with PAD. A National Veterans Health Administration population-based study of 155,647 patients demonstrated that use of a high-intensity statin at the time of PAD diagnosis was associated with a significant reduction in both limb loss and mortality.[103]

In patients with persistently elevated LDL despite the maximally tolerated statin dose, consideration should be given to the addition of ezetimibe, which reduces LDL cholesterol absorption in the small intestine and has been shown to lower cardiovascular event rates.[104,105] For patients receiving maximally tolerated statin and ezetimibe who cannot reach the LDL goal, proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors, monoclonal antibodies that increase hepatic LDL receptors, can be added to decrease LDL, reduce cardiovascular events, and reduce the risk of major adverse lower extremity events.[105,106]

Hypertension Control

The primary goal of treating elevated blood pressure in patients with PAD is to reduce MACE; however, there are few specific trials evaluating blood pressure goals in patients with PAD. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin-receptor blockers have demonstrated benefit in reducing the risk of cardiovascular ischemic events in PAD patients.[46] Analysis of the PAD subgroup in the Heart Outcomes Prevention Evaluation (HOPE) trial found that patients treated with ramipril had a 25% reduction of MI, stroke, and cardiovascular death versus placebo.[107] However, in the Ongoing Telmisartan Alone and in Combination With Ramipril Global Endpoint Trial (ONTARGET), telmisartan had similar efficacy to ramipril in PAD patients with less angioedema, representing a role for angiotensin-receptor blockers as an alternative to ACE inhibitors.[108] Beyond that, it is clear that patients who consistently have SBP >140 mm Hg and diastolic blood pressure >90 mm Hg require antihypertensive medications, and cardiology guidelines increasingly support much lower targets.[109,110]

Smoking Cessation

In patients with PAD, smoking cessation is associated with decreased mortality and improved amputation-free survival.[45] Smoking status should be assessed at every visit, and patients should be counseled on quitting as well as provided options for pharmacologic therapy and referral to a smoking cessation program. Several studies have demonstrated that varenicline, bupropion, and nicotine replacement therapy, used alone or in combination, all increase smoking cessation rates.[63] Additionally, intensive smoking cessation intervention, consisting of behavioral and pharmacologic components, resulted in more successful smoking cessation at 6 months than minimal intervention (21.3% vs. 6.8%).[111]

Exercise

Exercise is the most effective noninterventional approach to reducing leg symptoms in patients with IC.[112] Exercise has been demonstrated to have benefits for patients with PAD, including increased calf blood flow, improved endothelial function, improved metabolic function, decreased inflammation, and improved walking distances.[112] A Cochrane review examining 32 RCTs, including 1835 patients with IC, concluded that exercise programs provided improved pain-free and maximum walking distance as compared with placebo or usual care.[113] Additionally, in a meta-analysis of 25 RCTs, supervised treadmill exercise was demonstrated to improve walking performance in PAD patients by approximately 180 m compared with no exercise.[114] As of 2017, the Centers for Medicare and Medicaid Services deemed that there was sufficient evidence for the benefit of supervised exercise therapy that beneficiaries with walking impairment secondary to PAD are eligible for insurance coverage of up to 36 sessions over a 12-week period.[115]

Although less effective, evidence also supports home-based walking exercise to improve walking performance as a reasonable alternative for patients without access to supervised exercise therapy.[116] General recommendations for patients are to perform a minimum of 45 to 60 minutes of exercise three times per week for 12 weeks, typically walking on a treadmill, and effort should be sufficiently intense to elicit claudication.

Cilostazol

Based on a Cochrane review of 16 RCTs, in addition to exercise, a 3-month trial of cilostazol (100 mg twice daily) is recommended to improve pain-free walking in patients with IC.[64] Cilostazol, a reversible phosphodiesterase IIIa inhibitor, acts as a vasodilator, inhibits platelet aggregation, and improves walking distance, but it is contraindicated in patients with congestive heart failure. Patient noncompliance may be attributable to commonly reported side effects of headache, diarrhea, dizziness, and palpitations.

Medical and lifestyle management are recommended as first-line treatment for PAD; however, in a retrospective review of 3829 patients undergoing elective open lower extremity bypass for IC, only 47.6% of patients were on optimal medical therapy before surgery.[117] Similar findings were observed among the 1404 CLTI patients enrolled in the PREVENT III trial, where 33% of patients were not on any antiplatelet therapy at the time of study entry, and 54% were not receiving lipid-lowering therapy.[118] This demonstrates opportunities for improvement in the preoperative management of PAD patients because patients who were treated with optimal therapy had a lower risk of postoperative mortality, MI, and readmission.[117]

INTERVENTIONAL MANAGEMENT OF PERIPHERAL ARTERIAL DISEASE

Revascularization is defined as the restoration of perfusion to an area of ischemia. Goals of revascularization are to relieve pain, heal wounds, preserve a functional limb, and prevent a major amputation. Techniques for revascularization have continued to evolve though history. Open surgical revascularization techniques were pioneered by Alexis Carrel, who received the 1912 Nobel Prize for his methods of sewing blood vessels together to create vascular anastomoses. Jean Kunlin, in 1948, used these techniques to perform a femoral-popliteal bypass with saphenous vein, thereby ushering in the era of surgical revascularization for PAD.[119] Less invasive techniques for revascularization subsequently emerged. Sven-Ivar Seldinger described percutaneous vascular access over a wire and insertion of a soft catheter to opacify and visualize peripheral arteries in 1953.[120] The landmark contributions of Charles Dotter, including the introduction of percutaneous transluminal angioplasty in 1964, form the foundation of endovascular therapies today.[121]

Open surgical procedures for the treatment of PAD include inflow bypasses, infrainguinal bypasses, and endarterectomy. AIOD can be treated with direct aortic reconstruction with an aortofemoral bypass, most often using a prosthetic conduit, Dacron, or expanded polytetrafluoroethylene (PTFE), to bypass from the aorta to the common femoral artery (CFA), DFA, or superficial femoral artery (SFA). Extraanatomic reconstructions for the management of aortoiliac lesions include thoracofemoral bypass, axillofemoral bypass, and femoral-femoral bypass, which can be used to avoid infected regions or the hostile abdomen. *Infrainguinal bypass* is defined as any major arterial reconstruction using a bypass conduit, either autogenous or prosthetic, originating below the inguinal ligament. Short-segment occlusive disease involving the CFA and DFA is commonly treated with endarterectomy and patch angioplasty, in which the atherosclerotic plaque is peeled from the artery wall, and the arteriotomy is then repaired with a patch to prevent stenosis.

Endovascular techniques provide a less invasive method of revascularization. After percutaneous arterial access, a sheath is placed within the lumen of the vessel, through which wires directed by catheters are used to cross stenoses or occlusions remote to the access site. Once the lesion is traversed, balloon angioplasty, stenting, stent grafting, or atherectomy can then be used to restore luminal patency. Coating of balloons or stents with cytotoxic medications, such as paclitaxel or limus analogues, can decrease the risk of intraluminal neointimal formation. Such devices have been used clinically in PAD to decrease restenosis. Hybrid procedures, which combine both endovascular and open surgical techniques, can also be used in certain clinical scenarios.

Outcomes of revascularizations have historically reported patency rates. *Primary patency* is the term applied when patency of an intervention (bypass, angioplasty, stenting) is maintained over a specified time interval without reintervention. Successful reintervention on a patent but stenotic lesion is termed *primary assisted patency,* and restoration of patency of an occluded bypass or target vessel is termed *secondary patency*. In the setting of IC, measurement of walking distance has been used, whereas for CLTI, common end points include amputation, amputation-free survival, and MALE. Patient-centered outcome measures include a variety of qualitative instruments that examine quality of life, including the 12-Item Short-Form Survey (SF-12), EuroQol 5 Dimension (EQ-5D), and Vascular Quality of Life Questionnaire (VascuQoL).

TREATMENT OF ASYMPTOMATIC DISEASE AND INTERMITTENT CLAUDICATION

In the absence of a threatened bypass graft or stent, the Society for Vascular Surgery (SVS) guidelines recommend against invasive treatments for PAD in asymptomatic patients, regardless of hemodynamic measures or imaging findings.[64] The cornerstone of treatment for asymptomatic PAD is lifestyle change and medical therapy to address cardiovascular risk factors, with the goal of halting the progression of atherosclerosis in the limbs as well as in other vascular beds.

Despite having symptoms, patients with IC are still at relatively low risk of adverse outcomes, with a 5-year risk of limb amputation of 5% and a predicted 75% to 80% 5-year life expectancy.[64] The majority of patients with IC will maintain their current level of function or decline slowly; therefore, the preferred initial management strategy for such patients, in addition to optimal medical management, is supervised exercise therapy.[122] Approximately 20% to 30% of patients with IC will develop disability significant enough to warrant intervention.[64] In the treatment of patients with IC, interventions should only be undertaken in patients with lifestyle-altering symptoms, after failure of exercise and medical therapy, when anatomic factors are favorable, and prolonged patency and symptom relief are likely. The SVS issued appropriate use criteria for management of IC in 2022 to assist in appropriate shared decision-making with patients.

A systematic review of 10 RCTs that included 1087 patients with IC found that endovascular revascularization did not provide significant benefit as compared with supervised exercise alone in improvement in functional performance or quality-of-life metrics.[123] However, in patients with IC secondary to aortoiliac disease in the Claudication Exercise versus Endoluminal Revascularization (CLEVER) Trial, there was benefit to both supervised exercise and endovascular revascularization in improvement of functional status and quality of life.[124,125]

The appropriate use criteria also provide guidance for the treatment of patients with severe lifestyle limitations and short walking distance IC. Selected, low-risk, nonsmoking patients on optimal medical therapy may benefit from invasive therapy.[122] Invasive interventions for femoropopliteal disease should be reserved for patients with severe lifestyle-limiting IC. In these patients, when treating the CFA, open endarterectomy will provide greater net benefit than endovascular intervention. Invasive treatment of the tibial arteries in patients with IC is of unclear benefit and can lead to worsening of PAD and increased risk of limb loss.[122]

TREATMENT OF CHRONIC LIMB-THREATENING ISCHEMIA

In contrast to patients with IC, patients with CLTI have a 50% 5-year mortality and a much higher amputation risk, based primarily on the limb stage at presentation.[21] Limb classification systems have evolved, but they historically included the Fontaine[126] classification system, based solely on clinical symptoms, and the Rutherford[127] classification system, based on clinical symptoms and noninvasive data, with separation of chronic and ALI.

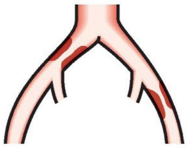
The Trans-Atlantic Inter-Society Consensus Document on Management of Peripheral Arterial Disease (TASC), published in 2000 and modified in 2007 as TASC II, sought to form a consensus in the classification and treatment of patients with PAD as well as provide a framework to compare revascularization strategies. TASC anatomically divided lesions into aortoiliac and femoral-popliteal segments, grouping lesion patterns based on the severity of occlusive disease (Figs. 103.5 and 103.6). In the treatment of both aortoiliac and femoral-popliteal lesions, surgical bypass was recommended for longer, more severe lesions (TASC C and D), whereas endovascular therapy was recommended for limited, focal disease (TASC A and B).[128]

The TASC classifications did not correlate with expected patency rates and outcomes of therapy,[69] and these older classification systems did not account for wound characteristics and presence and severity of infection, which are important considerations given the increasing prevalence of DM and the frequency of DFUs in the PAD population. To incorporate these factors, in 2014, the SVS developed the WIfI classification system, which is based on wound, ischemia, and foot infection at presentation and stratifies the degree of limb threat, thus guiding clinical management (Tables 103.1 and 103.2).[4] Each of the three factors is graded on an objective scale from 0 to 4, with the combinations grouped into four clinical stages (I–IV), which correlate with increasing 1-year risk of amputation. After intervention, treatment of infection, or suspected clinical deterioration, the WIfI score should be recalculated.[69]

A meta-analysis of 12 studies that included 2669 patients with CLTI demonstrated the prognostic value of the WIfI classification in predicting limb amputation.[129] A subset of five studies with 569 patients reported that 1-year amputation risk was shown to progressively increase with increasing WIfI stage: 0% for stage I, 8% (95% CI 3%–21%) for stage II, 11% (95% CI 6%–18%) for stage III, and 38% (95% CI 21%–58%) for stage IV.[129] A recent

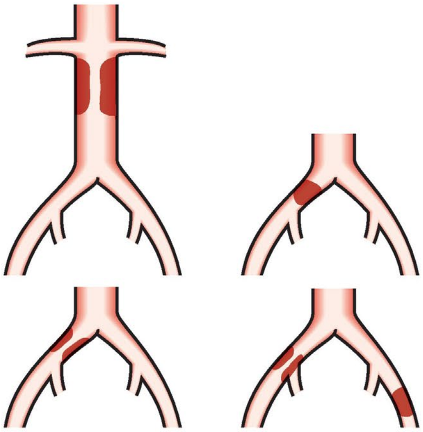
Type A lesions

- Unilateral or bilateral stenoses of CIA
- Unilateral or bilateral single short (≤3 cm) stenosis of EIA



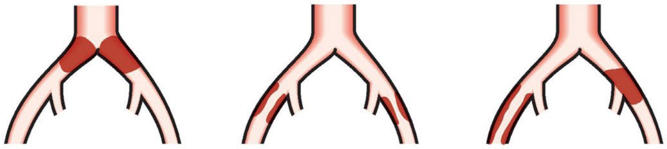
Type B lesions

- Short (≤3 cm) stenosis of infrarenal aorta
- Unilateral CIA occlusion
- Single or multiple stenosis totaling 3-10 cm involving the EIA not extending into the CFA
- Unilateral EIA occlusion not involving the origins of internal iliac of CFA



Type C lesions

- Bilateral CIA occlusions
- Bilateral EIA stenoses 3-10 cm long not extending into the CFA
- Unilateral EIA stenosis extending into the CFA
- Unilateral EIA occlusion that involves the origins of internal iliac and/or CFA
- Heavily calcified unilateral EIA occlusion with or without involvement of origins of internal iliac and/or CFA



Type D lesions

- Infrarenal aortoiliac occlusion
- Diffuse disease involving the aorta and both iliac arteries requiring treatment
- Diffuse multiple stenoses involving the unilateral CIA, EIA, and CFA
- Unilateral occlusions of both CIA and EIA
- Bilateral occlusion of EIA
- Iliac stenoses in patients with AAA requiring treatment and not amenable to endograft placement or other lesions requiring open aortic or iliac surgery

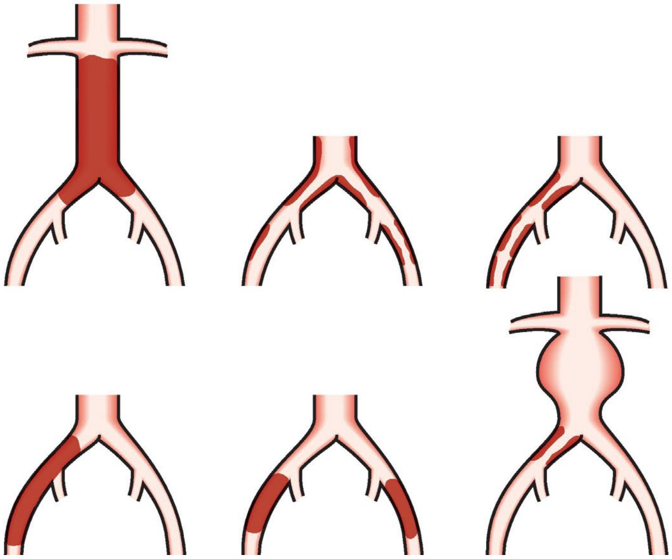


FIGURE 103.5 Trans-Atlantic Inter-Society Consensus Document on Management of Peripheral Arterial Disease classification of aortoiliac lesions. *AAA,* Abdominal aortic aneurysm; *CFA,* common femoral artery; *CIA,* common iliac artery; *EFA,* external femoral artery; *EIA,* external iliac artery. (From Norgren L, Hiatt WR, Dormandy JA, et al. TASC II Working Group. Inter-society consensus for the management of peripheral arterial disease [TASCII]. *J Vasc Surg.* 2007;45[suppl S]:S5-S61.)

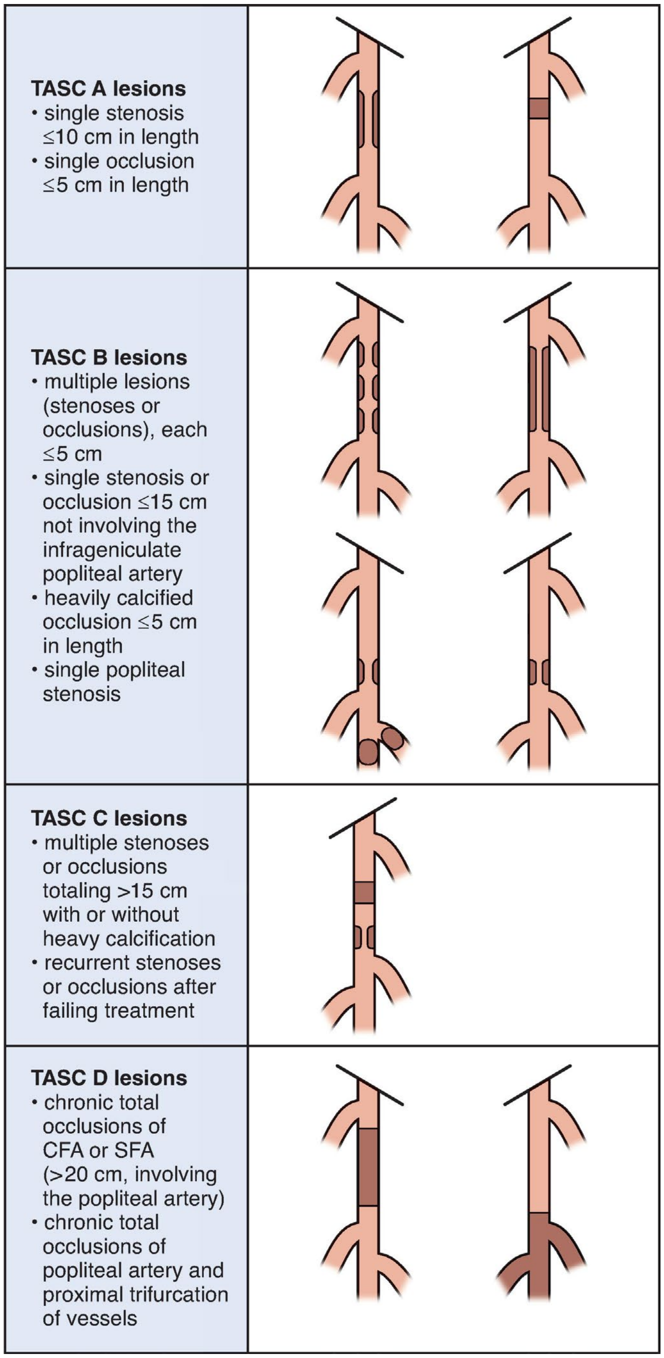

TASC A lesions
• single stenosis ≤10 cm in length
• single occlusion ≤5 cm in length
TASC B lesions
• multiple lesions (stenoses or occlusions), each ≤5 cm
• single stenosis or occlusion ≤15 cm not involving the infrageniculate popliteal artery
• heavily calcified occlusion ≤5 cm in length
• single popliteal stenosis
TASC C lesions
• multiple stenoses or occlusions totaling >15 cm with or without heavy calcification
• recurrent stenoses or occlusions after failing treatment
TASC D lesions
• chronic total occlusions of CFA or SFA (>20 cm, involving the popliteal artery)
• chronic total occlusions of popliteal artery and proximal trifurcation of vessels

FIGURE 103.6 Trans-Atlantic Inter-Society Consensus Document on Management of Peripheral Arterial Disease *(TASC)* classification of femoral-popliteal lesions. *CFA,* Common femoral artery; *SFA,* superficial femoral artery. (From Norgren L, Hiatt WR, Dormandy JA, et al. TASC II Working Group. Inter-society consensus for the management of peripheral arterial disease [TASCII]. *J Vasc Surg.* 2007;45[suppl S]:S5-S61.)

study found that presenting WIfI stage is also associated with long-term risk of major amputation and death after infrainguinal revascularization, with freedom from major amputation or death at 2 years in patients with WIfI stage 4 limbs reported to be 71% ± 3.7% and 68% ± 3.5%, respectively.[130]

The Global Vascular Guidelines recommend revascularization in the following clinical scenarios: symptomatic patients with severe (WIfI grade 3) ischemia and patients with advanced tissue loss or infection (WIfI stage 4) in the presence of moderate to severe ischemia (grade 2 and 3). Revascularization should be considered in those with intermediate limb-threat (WIfI stages 2 and 3) and moderate to severe ischemia (grade 2 and 3), advanced limb threat (WIfI stage 4) with moderate ischemia (grade 1), and those with intermediate limb threat and moderate ischemia if the wound fails to reduce in size by ≥50% in 4 weeks despite optimal wound care, management of infection, and pressure offloading.[69]

When deciding on a treatment strategy in patients felt to benefit from revascularization, in addition to the limb stage, the estimated risk for intervention, life expectancy, and underlying vascular anatomy are integral components of the decision-making process. To aid in clinical decision-making, an integrated approach termed *PLAN* (**P**atient risk estimation, **L**imb staging, **AN**atomic pattern of disease) is recommended (Fig. 103.7).[69]

Estimation of operative risk and life expectancy are important factors to assess potential benefit of intervention. A predictive model based on the preoperative variables of 38,470 CLTI patients undergoing infrainguinal revascularization in the Vascular Quality Initiative (VQI) stratified patients into three risk groups: low-risk (>97% 30-day survival and >70% 2-year survival), medium-risk (95%–97% 30-day survival, 50%–70% 2-year survival), and high-risk (<95% 30-day survival, <50% 2-year survival).[131] Among all three models, independent predictors of death were found to be age >80 years, oxygen-dependent chronic obstructive pulmonary disease (COPD), stage V CKD, and bedbound status.[131] Other independent predictors include advanced age, CKD, CAD, congestive heart failure (CHF), DM, smoking, CVD, tissue loss, body mass index (BMI), dementia, and functional status.[69] The Global Vascular Guidelines group CLTI patients into average (anticipated periprocedural mortality <5% and estimated 2-year survival >50%) and high-risk (anticipated periprocedural mortality ≥5% and estimated 2-year survival ≤50%) cohorts.

Before any revascularization for CLTI, the patient's medical comorbidities should be evaluated and optimized. Although there are limited data specific to the management of CLTI patients with frailty, a geriatrics assessment and prehabilitation may also be indicated.[132] In the presence of a stable wound, it is appropriate to take time for medical optimization; however, in patients with ischemic rest pain or evolving wound, time is tissue, and intervention should only be delayed in patients with unstable angina or uncontrolled CHF.

With the availability of both open and endovascular strategies for revascularization, it is important to consider the underlying indication and technical details to help with operative planning. An advantage of endovascular revascularization is that most interventions can be performed without general anesthesia, using local anesthesia and conscious sedation, with minimal blood loss and reduced physiologic stress to the patient. However, results of endovascular intervention are often less durable than surgical bypass. Restenosis caused by neointimal hyperplasia is common after endovascular therapy, especially for complex and calcified lesions. Patients with CLTI often have long-segment and multilevel disease, which have inferior patency rates after endovascular intervention; however, the period of patency and improved perfusion may be long enough to heal an ischemic wound and may not require further intervention even in the setting of arterial reocclusion (Fig. 103.8). Conversely, patients with IC or ischemic rest pain will often have recurrence of symptoms when the intervention fails.[133]

Although the limb is staged with WIfI, the anatomic pattern and severity of the disease are classified using the Global Limb Anatomic Staging System (GLASS), and the availability of autogenous conduit is determined. Aortoiliac disease is assessed and corrected if present. GLASS then classifies the disease from groin to foot using high-quality, usually angiographic, images to select the target arterial path (TAP) that is most likely to achieve inline flow to the foot. The stenoses and occlusions in the femoropopliteal and infrapopliteal segments are both graded on severity using a scale from 0 to 4 based on lesion length as well as ostial involvement and presence of significant calcification (Figs. 103.9 and 103.10). Pedal anatomy is taken into consideration with a modifier to describe the inframalleolar arteries (Fig. 103.11). The grades are then combined to create an anatomic stage ranging from I to III based on estimates of technical failure and 1-year limb-based patency (Table 103.3).

Patients with GLASS stage III have been demonstrated to have an almost fourfold increased risk of immediate technical failure after endovascular intervention as compared with GLASS stage I and II (RR 3.96, 95% CI 1.96–7.98) and an almost twofold risk of major amputation (RR 1.84, 95% CI 1.18–2.87).[134] Although worse outcomes in amputation-free survival, limb salvage rate, and MALE were observed after endovascular intervention in patients with GLASS stage III as compared with GLASS stages I and II, no difference was seen between the stages in patients undergoing bypass surgery.[135] This suggests that advanced GLASS stage favors bypass over endovascular revascularization (Fig. 103.12).

SELECTION OF REVASCULARIZATION STRATEGY

In patients with AIOD, the Trans-Atlantic Inter-Society Consensus (TASC) II guidelines published in 2007 recommended open surgical revascularization for TASC C and D lesions.[128] However, improvements in endovascular techniques have led to increased endovascular treatment of more complex occlusive lesions with high rates of technical success and secondary patency comparable to surgical repair.[136]

In comparing open surgical versus endovascular revascularization for AIOD, a meta-analysis of 11 observational studies that included 4030 patients with TASC C and D lesions found significantly improved primary patency at 50 months in the surgical group (91% vs. 81%, HR 0.51, CI 0.36–0.73, $p = 0.0002$).[137] Both techniques had similar limb salvage and secondary patency rates, and reported 30-day mortality rates were 2.9% in the open aortofemoral bypass group and 1.4% in the endovascular group.[137] The addition of a femoral endarterectomy has been shown to improve the primary patency of endovascular interventions for treatment of the aortoiliac segment, highlighting the importance of outflow to maintaining patency.[137] In an evolution from the 2007 TASC II classifications, the 2019 Global Vascular Guidelines support GLASS, which is a more nuanced classification. They suggest an endovascular-first approach for the treatment of CLTI in patients with AIOD from moderate to severe (GLASS stage IA) disease and a surgical reconstruction for average-risk patients with extensive (GLASS stage II) disease or after failed endovascular revascularization.[69]

In infrainguinal occlusive disease, there are three RCTs in patients with CLI that guide evidence-based treatment. Published in 2005, the Bypass Versus Angioplasty in Severe Ischaemia of the Leg (BASIL) trial, a randomized, controlled, multicenter trial

IV. **WIfI** score
V. W: **Wound/clinical category**
VI. SVS grades for rest pain and wounds/tissue loss (ulcers and gangrene):
VII. 0 (ischemic rest pain, ischemia grade 3, no ulcer), 1 (mild), 2 (moderate), 3 (severe)

GRADE	ULCER	GANGRENE
0	No ulcer	No gangrene
Clinical description: ischemic rest pain (requires typical symptoms + ischemia grade 3); no wound.		
1	Small, shallow ulcer(s) on distal leg or foot; no exposed bone, unless limited to distal phalanx	No gangrene
Clinical description: minor tissue loss. Salvageable with simple digital amputation (1 or 2 digits) or skin coverage.		
2	Deeper ulcer with exposed bone, joint, or tendon; generally not involving the heel; shallow heel ulcer, without calcaneal involvement	Gangrenous changes limited to digits
Clinical description: major tissue loss salvageable with multiple (≥3) digital amputations or standard TMA ± skin coverage.		
3	Extensive, deep ulcer involving forefoot and/or midfoot; deep, full thickness heel ulcer ± calcaneal involvement	Extensive gangrene involving forefoot and/or midfoot; full thickness heel necrosis ± calcaneal involvement
Clinical description: extensive tissue loss salvageable only with a complex foot reconstruction or nontraditional TMA (Chopart or Lisfranc); flap coverage or complex wound management needed for large soft tissue defect.

TABLE 103.1 Society for Vascular Surgery (SVS)Wound, Ischemia, and Foot Infection (WIfI) Lower Extremity Threatened Limb Classification System—cont'd

CLINICAL MANIFESTATION OF INFECTION	SVS	IDSA/PEDIS INFECTION SEVERITY
No symptoms or signs of infection	0	Uninfected
Infection present, as defined by the presence of at least two of the following items: • Local swelling or induration • Erythema >0.5 to ≤2 cm around the ulcer • Local tenderness or pain • Local warmth • Purulent discharge (thick, opaque to white, or sanguineous secretion)		
Local infection involving only the skin and the subcutaneous tissue (without involvement of deeper tissues and without systemic signs as described below)	1	Mild
Exclude other causes of an inflammatory response of the skin (e.g., trauma, gout, acute Charcot neuroosteoarthropathy, fracture, thrombosis, venous stasis)		
Local infection (as described above) with erythema >2 cm, or involving structures deeper than skin and subcutaneous tissues (e.g., abscess, osteomyelitis, septic arthritis, fasciitis), and no systemic inflammatory response signs (as described below)	2	Moderate
Local infection (as described above) with the signs of SIRS, as manifested by two or more of the following: • Temperature >38°C or <36°C • Heart rate >90 beats/min • Respiratory rate >20 breaths/min or $PaCO_2$ <32 mm Hg • White blood cell count >12,000 or <4000 cu/mm or 10% immature (band) forms	3	Severe[a]

ABI, Ankle-brachial index; *IDSA,* Infectious Diseases Society of America; $PaCO_2$, partial pressure of arterial carbon dioxide; *PVR,* pulse volume recording; *SIRS*, systemic inflammatory response syndrome; *SPP,* skin perfusion pressure; $TcPO_2$, transcutaneous oximetry; *TMA,* transmetatarsal amputation; *TP,* toe pressure.

I: Ischemia

Hemodynamics/perfusion: Measure TP or $TcPO_2$ if ABI incompressible (>1.3).

SVS grades: 0 (none), 1 (mild), 2 (moderate), and 3 (severe).

Patients with diabetes should have TP measurements. If arterial calcification precludes reliable ABI or TP measurements, ischemia should be documented by $TcPO_2$, SPP, or PVR. If TP and ABI measurements result in different grades, TP will be the primary determinant of ischemia grade. Flat or minimally pulsatile forefoot PVR = grade 3.

fI: Foot Infection

SVS grades: 0 (none), 1 (mild), 2 (moderate), and 3 (severe: limb and/or life threatening).

SVS adaptation of IDSA and International Working Group on the Diabetic Foot (IWGDF) perfusion, extent/size, depth/tissue loss, infection, sensation (PEDIS) classifications of diabetic foot infection.

[a] Ischemia may complicate and increase the severity of any infection. Systemic infection may sometimes manifest with other clinical findings, such as hypotension, confusion, vomiting, or evidence of metabolic disturbances (e.g., acidosis, severe hyperglycemia, new-onset azotemia).

From Lipsky BA, Berendt AR, Cornia PB, et al. 2012 Infectious Diseases Society of America clinical practice guideline for the diagnosis and treatment of diabetic foot infections. *Clin Infect Dis*. 2012;54:e132-e173.

comparing open surgical bypass with autogenous vein to balloon angioplasty in the treatment of femoral-popliteal disease, reported no significant differences between the two groups in 6-month amputation-free survival.[138] However, among the 70% of patients who survived for 2 years after randomization, there was a significant increase in subsequent overall survival and a trend toward improved amputation-free survival in the patients initially undergoing open surgical bypass.[139] This highlights the importance of treatment durability and assessing life expectancy in the selection of revascularization strategy.

Almost two decades after the BASIL trial, two recent RCTs, the Best Endovascular Versus Best Surgical Therapy for Patients With Critical Limb Ischemia (BEST-CLI)[140] and the BASIL-2,[141] trial have sought to provide more evidence for the preferred revascularization strategy in patients with CLTI. BEST-CLI, a pragmatic international trial of 1830 patients completed across 150 centers, randomized patients to endovascular intervention versus open bypass surgery for the treatment of infrainguinal occlusive disease in patients who were candidates for both revascularization strategies. Patients were evaluated in two parallel cohorts depending on the availability of an adequate single-segment great saphenous vein (SSGSV), the best possible conduit for infrainguinal bypass. In the cohort of patients with SSGSV, open surgical bypass was associated with a significantly lower incidence of the composite primary outcome of MALE or all-cause death (42.6% vs. 57.4%, HR 0.68, 95% CI 0.59–0.79, $p < 0.001$).[140] These findings were attributable to a 65% increase in first major reinterventions in the endovascular group and a 27% reduction in limb amputation in the surgery group.[142] However, 20% to 45% of patients do not have adequate autogenous saphenous vein,[143] and among patients lacking optimal conduit, endovascular and open surgical therapy had similar rates of MALE and all-cause death.[140] The results from BEST-CLI support surgical revascularization as a first revascularization strategy in patients with adequate SSGSV and demonstrate that presence of an optimal conduit is an important factor to consider when determining a treatment strategy.

IDSA, Infectious Diseases Society of America; *PAD,* peripheral artery disease; *PEDIS,* perfusion, extent/size, depth/tissue loss, infection, sensation; *WIfI,* wound, ischemia, and foot infection.

Premises:

a. Increase in wound class increases risk of amputation (based on WIfI, PEDIS, University of Texas, and other wound classification systems).

b. PAD and infection are synergistic (Eurodiale); infected wound + PAD increases likelihood revascularization will be needed to heal wound.

c. Infection 3 category (systemic/metabolic instability): moderate to high risk of amputation regardless of other factors (validated IDSA infection guidelines).

Adapted from Mills JL, Sr., Conte MS, Armstrong DG, et al. The Society for Vascular Surgery lower extremity threatened limb classification system: risk stratification based on wound, ischemia, and foot infection (WIfI). *J Vasc Surg.* 2014;59:220-234.e1-e2.

BASIL-2, conducted in the United Kingdom, randomized 345 patients with CLTI requiring an infra-popliteal intervention, with or without an additional more proximal infrainguinal revascularization, to vein bypass or best endovascular treatment.[141] Whereas the primary end point used in BEST-CLI was MALE or death, amputation-free survival was the primary end point in BASIL-2. Among the patients included in this trial, a bypass-first revascularization strategy was associated with a 35% increase in major amputation or death (63% in vein bypass group had a major amputation or death vs. 53% in the endovascular group, adjusted HR 1.35 [95% CI 1.02–1.80], $p = 0.37$).[141] This result was driven by more deaths in the surgical treatment group.

Although these two trials seemingly report conflicting results, it is important to note that there are significant differences between them. The primary end points used were different. In BEST-CLI, MALE or all-cause death was used, which includes major amputation, death, and major reinterventions (new bypass, interposition graft, thrombectomy, or thrombolysis); minor reinterventions, such as angioplasty, stents, and surgical patch angioplasty, were excluded. Amputation-free survival used in BASIL-2 is dominated by mortality and does not account for reinterventions for unresolved or recurrent symptoms. In addition, the patients enrolled in these trials were very different. In BASIL-2, there were fewer females, non-Whites, and patients with ESRD. There were significantly higher rates of prior index limb revascularization and use of angioplasty alone, with less use of drug elution. Although technical failure rates of endovascular therapy were similar in both trials, rates of amputation, death, and periprocedural death were higher in BASIL-2. Further analysis is needed to harmonize the results of these trials and determine whether the seemingly disparate findings are related to patient factors or procedural factors or are a consequence of the difference in healthcare systems in North America and the United Kingdom.[144]

In patients with limited life expectancy or poor functional status, consideration should be given to palliative measures or primary amputation.

OPEN SURGICAL REVASCULARIZATION

Inflow Bypass Techniques

Aortofemoral Bypass

In patients of suitable risk with hemodynamically significant aortic and iliac stenosis or occlusions, open in-line revascularization can be accomplished using aorto-bifemoral bypass. The outflow targets, the CFAs or DFAs, are exposed bilaterally (Fig. 103.13). A longitudinal midline laparotomy, or less commonly a retroperitoneal incision, is performed, after which the transverse colon is elevated superiorly, and the small bowel is reflected to the patient's right to expose the aorta in the retroperitoneum. The optimal inflow site is typically just inferior to the renal arteries. Tunnels are

created between the aorta and the groins, deep to the colon and the ureters. Systemic heparin (70–100 units/kg) is administered, with a goal activated clotting time of >250 seconds. The aorta is cross-clamped distally and proximally. Preoperative review of available imaging should be used to identify a suitable location for clamp placement, with application of the clamp in a normal arterial segment whenever possible to avoid embolization of plaque.

A prosthetic conduit (Dacron or expanded PTFE) is generally used for reconstruction. Proper graft sizing is important to prevent sluggish flow and resulting formation of laminar thrombus, which has the potential to embolize. A 16-mm by 8-mm bifurcated graft is frequently used in males, whereas a 14-mm by 7-mm graft may be more suited to female anatomy. In cases of infection of a previously placed prosthetic conduit, after graft excision, in-line reconstruction can be performed using autogenous femoral veins as a neoaortoiliac system or using cryopreserved arteries or veins. Rifampin-soaked Dacron grafts are also used in primary reconstructions as well as in the setting of grafts infected with low-virulence organisms.

The proximal aortic anastomosis can be constructed in an end-to-end or end-to-side configuration. Although there is no clear evidence to demonstrate overall superiority of one technique over the other, certain anatomic factors should be considered. An end-to-end aortic anastomosis is generally preferred because of

improved in-line flow with reduced perianastomotic turbulence and avoidance of competitive flow. In this configuration, the graft lies flatter in the retroperitoneum, preventing kinking of the limbs and allowing for easier closure of the retroperitoneum over the graft to protect the prosthetic from the adjacent small bowel. Proponents of an end-to-end aortic anastomosis cite an older study comparing the two configurations that reported a 100% 3-year patency for end-to-end anastomoses as compared with 91.4% for end-to-side anastomoses. Additionally, an end-to-end approach is needed in the presence of a concomitant abdominal aortic aneurysm.

However, an end-to-side configuration may be preferred in patients to preserve flow in a patent inferior mesenteric artery (IMA) or accessory renal artery or to maintain pelvic perfusion in patients where an end-to-end anastomosis would result in limited retrograde flow to the internal iliac arteries (IIAs) as a result of the presence of external iliac artery (EIA) disease. In this configuration, an approximately 3-cm longitudinal arteriotomy is created

After selection of the target arterial path (TAP), the segmental femoropopliteal *(FP)* and infrapopliteal *(IP)* grades are determined from high-quality angiographic images. Using the table, the combination of FP and IP grades is assigned to GLASS stages I to III, which correlate with technical complexity (low, intermediate, and high) of revascularization.
From Conte MS, Bradbury AW, Kolh P, et al. Global vascular guidelines on the management of chronic limb-threatening ischemia. *J Vasc Surg.* 2019;69:3S-125S.e40.

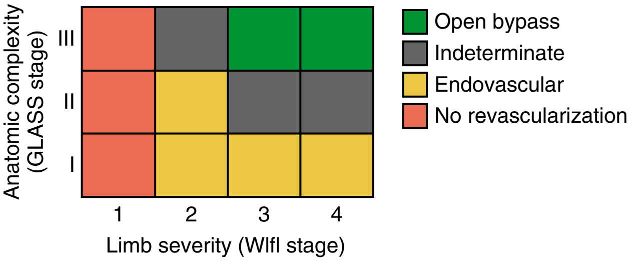

FIGURE 103.12 Preferred initial revascularization strategy for infrainguinal disease in average-risk patients with suitable autologous vein conduit available for bypass. Revascularization is considered rarely indicated in limbs at low risk (wound, ischemia, and foot infection *[WIfI]* stage 1). Anatomic stage (y-axis) is determined by the Global Limb Anatomic Staging System *(GLASS);* limb risk (x-axis) is determined by WIfI staging. The dark-gray shading indicates scenarios with least consensus (assumptions inflow disease either is not significant or is corrected; absence of severe pedal disease [i.e., no GLASS P2 modifier]). (From Conte MS, Bradbury AW, Kolh P, et al. Global vascular guidelines on the management of chronic limb-threatening ischemia. *J Vasc Surg.* 2019;69:3S-125S.e40.)

as cephalad as possible, and the graft is beveled 60 degrees (anterior to posterior). Reimplantation of a patent IMA or accessory renal artery onto the main body of the graft or an additional bypass to a patent internal iliac artery to maintain pelvic perfusion can be performed if an end-to-end configuration is still preferred.

For an end-to-end proximal anastomosis, the aorta is transected, and the proximal anastomosis is created with running 3-0 polypropylene suture. In cases of significant disease at the proximal anastomosis, an interrupted, pledgeted suture technique can be employed to reinforce residual thin adventitia after endarterectomy of the proximal aortic cuff. The distal aortic stump is then ligated in two layers. The graft limbs are passed through the retroperitoneal tunnels into the groin, taking care not to twist or kink the limbs.

In constructing the femoral anastomoses, attention should be given to clamp application, location of the anastomosis, and suturing technique. When posterior plaque is present, it is recommended to use a clamp that compresses the artery in the anterior-posterior direction, rather than from side to side, to avoid plaque disruption. Proximal balloon control can also be used to avoid

FIGURE 103.13 (A) The femoral triangle is bordered by the inguinal ligament and the adductor magnus and sartorius muscles. The *dashed line* is the proposed skin incision for exposure of the common femoral artery (CFA), proximal superficial femoral artery, and deep femoral artery (DFA). (B) The CFA lies lateral to the common femoral vein. The DFA exits posterolaterally. The great saphenous vein enters anteromedially. (From Chaikof EL, Cambria RP. Open surgical bypass of femoral-popliteal arterial occlusive disease. In: *Atlas of Vascular Surgery and Endovascular Therapy*. Philadelphia: Elsevier; 2014: Figure 44-2.)

clamping a heavily diseased vessel. In patients with normal femoral and distal runoff, a longitudinal arteriotomy in the distal CFA with a beveled end-to-side anastomosis created with running 5-0 Prolene suture is sufficient. However, in the presence of atherosclerotic disease affecting the DFA and SFA, profundaplasty has historically been demonstrated to preserve the long-term patency of both anatomic and extraanatomic grafts in patients with AIOD.[145,146] It is also common practice to position the hood of the distal anastomosis over the DFA origin to improve outflow in the presence of severe SFA disease or occlusion. In patients with multilevel, severe occlusive disease, adjunctive infrainguinal bypass graft may be necessary to ensure sufficient outflow to maintain graft patency as well as to provide sufficient relief of ischemic symptoms and sufficient perfusion for wound healing.

When suturing the distal anastomosis, the needle is generally directed from outside to inside on the graft and from inside to outside on the artery. This technique is used to reduce risk of creating an intimal flap and encourages eversion of the graft and native artery. Medial and lateral stay sutures can be placed to decrease the need for grasping a diseased artery with forceps. Before completion of the distal anastomoses, the graft is flushed, and arteries are back-bled to remove any thrombus or debris. Once the anastomoses are completed, anesthesia is alerted before clamp removal because reperfusion can result in hypotension. Depending on the patient's hemodynamic response, the clamp may need to be reapplied and gradually removed as the anesthesiologist augments the blood pressure.

Because aorto-bifemoral bypass has a risk of distal embolization, before closure, the adequacy of distal perfusion must be assessed. The quality of pulses and Doppler signals distal to the bypass graft and in the feet are evaluated, and the general appearance of the legs is examined. If no further interventions are required, heparin is reversed with protamine (1 mg/100 units of circulating heparin), and hemostasis is obtained. The abdomen is irrigated, and the retroperitoneum is closed over the proximal graft. In cases without sufficient tissue coverage over the graft, a tongue of omentum is mobilized to cover the graft and separate it from the adjacent bowel before closure of the abdomen. The groin incisions are irrigated and closed in layers.

Complications

Aorto-bifemoral bypass is an operation of considerable physiologic magnitude and is associated with an overall morbidity rate of approximately 30%.[147,148] Perioperative mortality rates from contemporary studies range from 0.8% to 2.3%, with the majority of deaths attributed to cardiovascular causes.[147,148] Other immediate complications include hemorrhage, intestinal ischemia, acute renal failure, MI, pulmonary complications, ALI, and wound-healing complications.[149] Late complications include graft thrombosis, aortoenteric fistula, anastomotic pseudoaneurysm, and graft infection[149] as well as incisional complications, including ventral hernia and small bowel obstruction.[150]

Extraanatomic Inflow Bypass Techniques

Thoracofemoral Bypass

Thoracofemoral bypass, using inflow from the thoracic aorta, has an estimated 3-year primary limb patency and freedom from MALE of 80% ± 10% and 70% ± 10%, respectively, and an estimated 5-year survival of 93% ± 5%.[151] Different approaches for thoracofemoral bypass have been described. With the patient positioned in the right lateral decubitus position, the upper torso is rotated 30 to 45 degrees, the left shoulder is elevated, and the hips are positioned as flat as possible. After standard femoral artery exposure, the aorta is exposed through a left thoracotomy at the seventh, eighth, or ninth interspace. The aortic anastomosis is created in an end-to-side fashion after placement of a partially occluding side-biting clamp using a 14-mm by 7-mm or 16-mm by 8-mm bifurcated Dacron graft if bypassing to both legs or a 10-mm graft for a unilateral bypass to the left groin. The graft is then tunneled through the retroperitoneum into the groins, and the distal anastomoses are completed.[151] Blind tunneling has been described; however, a left flank retroperitoneal counter incision is commonly used to create a lateral diaphragmatic defect under direct vision and to tunnel the graft through the retrofascial, preperitoneal space into the right groin. Alternatively, a left thoracoretroperitoneal incision extending from the eighth or ninth intercostal space to midline halfway between the umbilicus and pubis, with division of the left crus of the diaphragm, can be used for exposure.[151]

Thoracofemoral bypass is associated with a high rate of major complications, including wound infections, cardiac and respiratory complications, major stroke, ESRD, embolic events, graft occlusion, and major amputation, occurring in 31% of patients in a series of 154 cases in the VQI.[152]

Femoral-Femoral Bypass and Axillofemoral Bypass

Other extraanatomic bypasses using alternative sources of inflow, including the axillary and contralateral femoral arteries, have lower patency, but these reconstructive options are useful in patients with severe comorbid conditions or limited life expectancies because of the lower morbidity and mortality compared with direct aortic reconstruction. Five-year primary patency is reported to range from 51% to 84% for axillofemoral bypass grafts[128,153] and from 73% to 75% for femoral-femoral bypass grafts.[154]

A femoral-femoral bypass uses unilateral iliac inflow to perfuse both lower extremities. The femoral arteries are exposed in the standard fashion, and a subcutaneous, prefascial tunnel is created in an arc between the groins so as to prevent graft kinking.

Axillary-femoral bypasses depend on inflow from one axillary artery to perfuse the upper extremity as well as one, if not both, lower extremities. A weak brachial or radial pulse or lower measured blood pressure suggests the presence of a more proximal stenosis and should prompt further preoperative evaluation with CTA or DSA.

A transverse infraclavicular incision is created, after which the deep fascia is incised, and the pectoralis minor muscle is split to expose the first part of the axillary artery. A subcutaneous tunnel is then created from the axillary artery to the ipsilateral groin incision originating posterior to the pectoralis minor muscle. An 8-mm externally supported expanded PTFE graft can be used, and care is taken to permit some redundancy in the axilla to reduce traction on the anastomosis with arm abduction. The contralateral groin is then revascularized with a femoral-femoral bypass or use of a bifurcated graft.

Endarterectomy

Endarterectomy can be performed for revascularization of focal lesions of the CFA and DFA, in conjunction with an inflow or infrainguinal bypass, or as part of a hybrid procedure. The femoral artery is exposed through either a longitudinal or transverse incision in the groin; however, a longitudinal incision allows for extension of the incision if the lesion is found to involve the distal EIA proximally or proximal SFA or DFA distally. For plaques extending proximally, it may be necessary to partially divide the inguinal ligament to identify a nondiseased segment of EIA suitable for clamp placement. A longitudinal arteriotomy is created in the CFA and extended proximally and distally beyond the area of occlusive disease. The plaque is then elevated along with the intima and peeled from the vessel wall. Residual plaque present at the distal end of the endarterectomy site is secured with polypropylene tacking sutures. Once the endarterectomy site is cleared free of debris, the arteriotomy is closed by patch angioplasty to prevent stenosis, commonly using a bovine pericardial patch.

The presence of an SFA occlusion may compromise the patency of an inflow bypass; therefore, if a stenosis of the DFA is present, it is recommended to be corrected with profundaplasty at the time of the inflow procedure because the DFA is the main source of collateral blood flow to the lower extremity.[128]

To perform a profundaplasty, the arteriotomy is extended over the DFA—in the presence of a bulky plaque in the proximal DFA, an endarterectomy may also be required—and patch angioplasty is performed. More distal exposure of the DFA can be achieved by ligating crossing deep femoral vein branches.

Infrainguinal Bypass Techniques

Infrainguinal bypass techniques are used to treat occlusive disease of the femoral-popliteal segment and/or the tibial vessels. To optimize the success of a bypass, there must be adequate inflow and outflow, and the most optimal conduit should be used. The inflow and outflow for infrainguinal bypasses are determined based on the location of occlusive disease and are commonly assessed using lower extremity DSA. CTA may be used for assessment of inflow disease; however, its utility in identification of an outflow target may be limited by the presence of small, calcified vessels. MRA and duplex ultrasound may also be used for preoperative planning.

Inflow must be sufficient to support graft patency. In a patient with a palpable ipsilateral femoral pulse and triphasic CFA Doppler waveforms, inflow is likely to be adequate. Additional imaging should be obtained in patients with an absent femoral pulse or abnormal Doppler waveform to assess the need for treatment of aortoiliac or CFA disease in conjunction with infrainguinal bypass. Revascularization of the inflow arteries can be accomplished with open or endovascular techniques.

The distal target should be the most proximal vessel distal to a hemodynamically significant stenosis that has runoff to the foot via at least one tibial artery. Distal target artery selection in patients with CLTI requires views of the foot, both anteroposterior and lateral, because these patients often require a tibial, DP, or plantar artery target (Fig. 103.14).

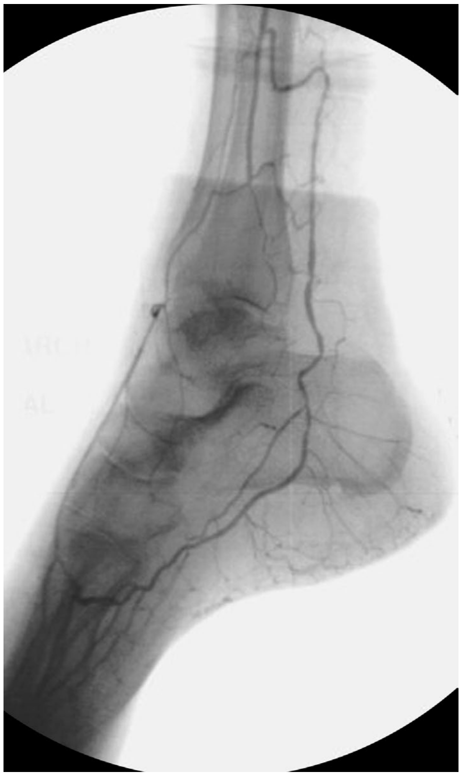

FIGURE 103.14 Lateral foot view obtained by distal selective superficial femoral arterial catheter injection identifies excellent collaterals from the distal peroneal artery to both the dorsal pedal and posterior tibial circulations. (From Mills JL. Infrainguinal disease: surgical treatment. In: Sidawy AN, Perler BA, eds. *Rutherford's Vascular Surgery and Endovascular Therapy*. 9th ed. Philadelphia: Elsevier; 2019:1438-1462.)

Bypass Conduit

Conduit selection is critical in the success of an infrainguinal bypass. Autologous conduits include GSV, small saphenous vein (SSV), arm (basilic and cephalic) vein, or composite vein consisting of multiple segments sewn together as one. Preoperative duplex ultrasound can be used to assess the availability of adequate caliber (≥3 mm) and quality (free of thrombosis or sclerosis and nonvaricose) autologous vein. In the absence of autologous vein, alternative conduits, including cryopreserved vein and prosthetic grafts, commonly expanded PTFE or Dacron, with or without heparin bonding, can be used.

Autologous vein is superior to all other conduits for infrainguinal bypass. Reported 5-year patency rates for GSV are approximately 75% to an above-knee popliteal target, 71% to a below-knee popliteal target, 69% to a tibial target, and 59% to a pedal target.[155–160] SSGSV has the best patency rates, and larger diameter is associated with improved outcomes.[161] However, historically, 20% to 45% of patients with lower extremity ischemia do not have adequate GSV.[162,163]

Single-segment vein is superior to spliced segments, and lower extremity veins are superior to arm veins. Reported 5-year primary and secondary patency rates for SSV are 53% and 76%, respectively, and 39% and 67%, respectively, for arm vein.[143] However, in the absence of GSV, alternative autologous (SSV, arm vein, and spliced vein conduits) and nonautologous biologic (cryopreserved vein and arterial graft) conduits were not demonstrated to have benefit over prosthetic grafts in patency or MALE among 22,671 lower extremity bypass procedures with infrageniculate targets in the VQI.[164]

Numerous studies have evaluated the use of prosthetic grafts. In comparing saphenous vein to expanded PTFE bypasses above the knee, a retrospective review of 25 studies reported a 2-year primary patency for venous bypasses of 81% versus 67% for PTFE, and at 5 years, the patency of venous bypasses was 69% compared with 49% in the PTFE group.[165] PTFE is the most commonly used prosthetic graft; however, a meta-analysis including eight RCTs comparing Dacron versus PTFE for above-the-knee popliteal bypasses found similar primary patency at 12 months but improved primary patency with Dacron at 24, 36, and 60 months (RR 0.79, $p = 0.003$; RR 0.80, $p = 0.03$; RR 0.85, $p = 0.02$).[166] Among patients included in the VOYAGER-PAD trial, open infrainguinal bypass with a prosthetic conduit was associated with a 2.5-fold increase in unplanned limb revascularization (adjusted HR 2.53, 95% CI 1.65–3.90, $p < 0.001$) and a 3-fold risk of ALI (adjusted HR 3.07, 95% CI 1.84–5.11, $p < 0.001$) compared with a venous conduit.[167] Because of these inferior patency rates, it is generally recommended to avoid infrainguinal bypass with prosthetic for the treatment of IC because graft failure has the potential to convert a patient with stable IC to a patient with ALI.

Adjuncts, including vein patches, cuffs, and distal AV fistulas, have been used in attempts to improve the patency of prosthetic grafts. However, a Cochrane review of prosthetic infrageniculate bypasses found that a vein cuff at the distal anastomosis improved primary patency but did not result in reduced rates of limb loss, and no benefit was observed for the creation of an arteriovenous (AV) fistula.[168]

Cryopreserved grafts have demonstrated poor long-term patency. One study of cryopreserved saphenous vein conduits for infrainguinal revascularization had a reported 5-year primary patency of 38.6% and a 50.2% 5-year limb salvage rate,[169] whereas an earlier study reported an 18% primary patency rate and a 71% limb salvage rate at 2 years.[170] For infrageniculate bypasses in patients with CLTI, cryopreserved arterial allografts have a 52% 1-year primary patency.[171] Despite these disappointing results, select patients without autogenous vein may benefit from the use of a cryopreserved graft because patency may be long enough to provide sufficient wound healing.

Bypass Technique

When ipsilateral GSV is available, it is harvested through a medial skin incision beginning two fingerbreadths lateral to the pubic tubercle. Preoperative ultrasound can be used to assess the quality and caliber of the vein and to mark the location on the skin directly over the vein to prevent creation of skin flaps during dissection that can compromise wound healing. The GSV is exposed from the saphenofemoral junction to a point distally that provides sufficient length for the planned bypass. Once exposed, side branches are ligated with silk ties, taking care to leave a short stump so as prevent narrowing of the vessel lumen. Once sufficient length has been obtained, the vein is ligated caudal to the saphenofemoral junction. Gentle distention of the vein with heparinized saline or a solution of autologous blood mixed with heparin and papaverine allows for identification of stenotic segments and as avulsed branches, which are then repaired with longitudinally oriented 7-0 polypropylene sutures. The vein is then stored in heparinized saline.

Because of presence of the venous valves, the GSV is then either reversed in orientation or the valves are lysed with a valvulotome. Angioscopy can be used to evaluate the quality of the vein and assess the adequacy of valve lysis. Nonreversed vein bypasses allow for optimizing the size to match the native artery diameters. An alternative to GSV harvest is an in situ GSV bypass. The GSV is mobilized toward the planned proximal and distal arterial anastomoses, the proximal anastomosis is completed, the valves are lysed with a valvulotome under arterial pressure, and large side branches are ligated before performing the distal anastomosis. After completion of the distal anastomosis, the graft is assessed for continuous Doppler flow with compression, which indicates the presence of an AV fistula and need for additional branch ligation. Advantages of this technique include avoiding full-length harvest and optimizing size match to the native artery diameters. Nevertheless, there is no evidence to support a preferred bypass configuration.[69]

Common sites of inflow for an infrainguinal bypass are the CFA, DFA, SFA, popliteal artery, and although less common, tibial artery. Distal origin grafts have acceptable long-term patency when vein conduit is used and if there are no untreated hemodynamically significant lesions proximal to the graft origin.[172] Bypasses originating from a distal origin have the advantage of requiring shorter conduit length. The cumulative 5-year patency rate of autogenous grafts originating distal to the groin is reported to be 62%, and significantly improved patency was observed in the subset of patients with DM (73% for the DM subgroup and 45% in the group without DM [$p < 0.001$]).[173] When an adjunctive inflow procedure has been performed, the bypass graft can originate on the hood of the proximal bypass or from an arterial patch. In patients undergoing reoperative revascularization, the lateral approach to the DFA can be used to avoid dense scar in the femoral triangle.

The distal target should be the most proximal vessel that will provide adequate runoff to the lower limb and foot. Distal target vessels include the above-knee popliteal, below-knee popliteal, tibial, and pedal vessels. In the setting of advanced WIfI stage (3 and 4), the distal target should ideally provide continuous in-line flow to the ankle and foot, although ATA, PTA, and peroneal bypasses have been shown to perform equally well for limb salvage.[69]

The CFA is approached through a longitudinal or transverse incision in the inguinal region just medial to the sartorius muscle. Longitudinal incisions allow for extension of the incision over the EIA proximally and the SFA and DFA distally if additional exposure is required. If less extensive exposure of the femoral artery is anticipated, a transverse incision can be performed, which may be associated with a lower risk of infectious complications.[174] In patients undergoing reoperative revascularization, the lateral approach to the DFA, through an incision placed lateral to the sartorius, can be used to avoid dense scar in the femoral triangle.

The popliteal artery is exposed through a medial approach, deepening the saphenectomy incision if present. An incision in the distal anteromedial thigh is created to expose the above-knee popliteal artery, after which the sartorius muscle is retracted inferiorly and the adductor muscle group is reflected superiorly. The below-knee popliteal artery is approached through an incision posterior to the tibia in the medial upper calf, after which the crural fascia is incised and medial head of the gastrocnemius muscle is retracted posteriorly. For more proximal exposure, the pes anserinus, the conjoined tendons of the semitendinosus, semimembranosus, and gracilis, can be divided.

When exposing the tibial vessels, there are various approaches depending on the location of the distal target and planned route of tunneling. The PTA and proximal to midperoneal arteries are approached through a medial incision in the lower leg 2 cm posterior to the edge of the tibia (Fig. 103.15). The soleus muscle fibers are mobilized from the tibia, and the flexor digitorum longus is retracted superiorly. The PTA can then be identified in this space. The PTA and veins are retracted inferiorly, and the incision is deepened to locate the peroneal artery on the anterior surface of the flexor hallucis longus. The distal peroneal artery can be exposed laterally through an incision over the distal fibula, after which a short segment of fibula is resected to expose the peroneal artery directly beneath. To expose the ATA, a medial incision is created midway between the tibia and fibula, the crural fascia is incised, and the artery is identified in the plane between the tibialis anterior superiorly and extensor digitorum longus inferiorly. The terminus of the PTA, the common plantar artery, is exposed through an incision just inferior to the medial malleolus, and the flexor retinaculum is divided (Fig. 103.16).[175] An incision on the dorsum of the foot lateral to the extensor hallucis longus is used to expose the DP, the terminus of the ATA, immediately deep to the edge of the extensor retinaculum. Pedal reconstructions with a DP target have primary patency and limb salvage rates of 56.8% and 78.2%, respectively, at 5 years and 37.7% and 57.7% at 10 years.[160] A series of plantar and tarsal branch bypasses reported a 41% primary patency and 69% limb salvage rate at 5 years, demonstrating the durability of pedal bypass for limb salvage.[176]

A tunnel is created between the proximal and distal targets, either anatomically along the vessel being bypassed or subcutaneously. Anatomic bypasses have the advantage of requiring a shorter vein conduit, and the location in a deeper anatomic plane may avoid exposure of the graft in cases of infection. Bypasses to the ATA can be tunneled anatomically; however, this requires tunneling through the interosseous membrane to tunnel the bypass from medial to lateral. A subcutaneous bypass is often useful in

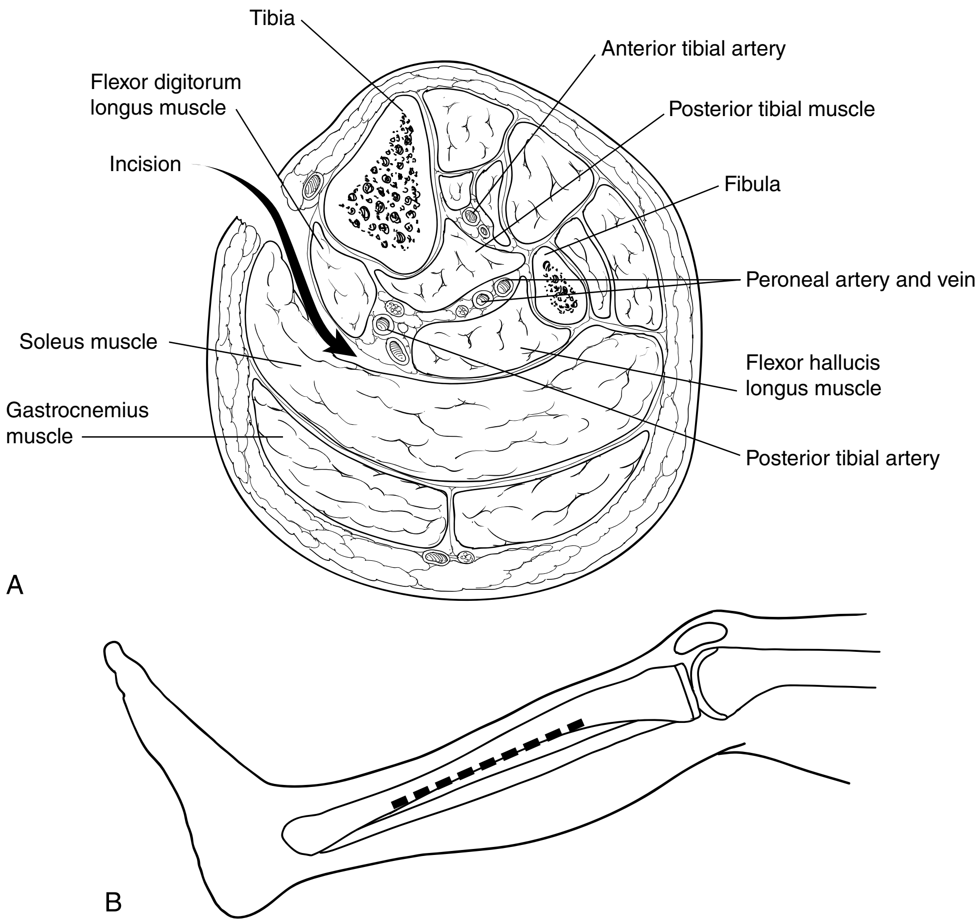

FIGURE 103.15 Exposures of both the peroneal and the posterior tibial arteries are performed via medial calf incision. The posterior tibial artery is encountered between the soleus muscle and the flexor digitorum longus muscle. The peroneal artery is encountered deeper in the wound on the anterior surface of the flexor hallucis longus muscle, as depicted. (A) Cross-section of right lower leg. (B) Location of medial calf incision for exposure of the posterior tibial and peroneal arteries. (From Chaikof EL, Cambria RP. Direct surgical repair of tibial-peroneal arterial occlusive disease. In: *Atlas of Vascular Surgery and Endovascular Therapy*. Philadelphia: Elsevier; 2014.)

reoperative cases to avoid areas of scarring, and the superficial location makes it easily accessible if future intervention is required. When tunneling grafts in the superficial plane laterally, it is important to avoid the area around the fibular head to minimize risk of common peroneal nerve injury as well as to cross the knee at the midpoint of the lateral femoral condyle to prevent compression and stretching of the graft with knee flexion.

Routine completion studies after bypass are not recommended.[177] However, if there is a concern based on distal graft pulse palpation and Doppler flow assessment with and without graft compression, additional studies should be considered to identify any complications. Options include completion DSA, intraoperative duplex scanning, and angioscopy. Unfortunately, there is no clear consensus on when to use completion imaging, and several studies have failed to demonstrate benefit.[177,178] An analysis of the use of completion imaging among 37,919 lower extremity bypass procedures in the VQI reported no association between use of completion imaging and reduced rates of MALE or loss of primary patency at 1 year.[179]

Complications

Complications after infrainguinal bypass include wound complications, graft occlusion, graft infection, bleeding, and death. Reported 30-day complication rates among the 1404 patients undergoing infrainguinal bypass with vein in the PREVENT III trial were as follows: death (2.7%), graft occlusion (5.2%), major wound complication (4.8%), MI (4.7%), major amputation (1.8%), and graft hemorrhage (0.4%).[180] Late complications include infection, graft stenosis or occlusion, aneurysmal degeneration of the graft, and lymphedema.

The incidence of early bypass graft failures (<30 days) has been reported to be between 4% and 7.4%.[181] Early graft failures are typically due to a technical complication, such as an imperfect anastomosis, clamp injury, compression or kinking of the graft, graft redundancy, poor quality conduit, or residual valve leaflets. Hypercoagulable and low-flow states, as well as poor distal outflow, can also contribute to early graft thrombosis. Risk factors associated with early graft thrombosis include female sex, history of a prior vascular procedure, emergent or limb salvage indication, current smoking, infrapopliteal anastomosis, graft diameter <3 mm, and use of composite graft and platelets >400,000.[181] In the setting of an early graft failure, outcomes are more favorable when the culprit lesion can be identified and corrected.

Intermediate and late graft occlusion can result from development of intimal hyperplasia, which has a peak incidence in the first 18 months postoperatively; anastomotic aneurysm; and

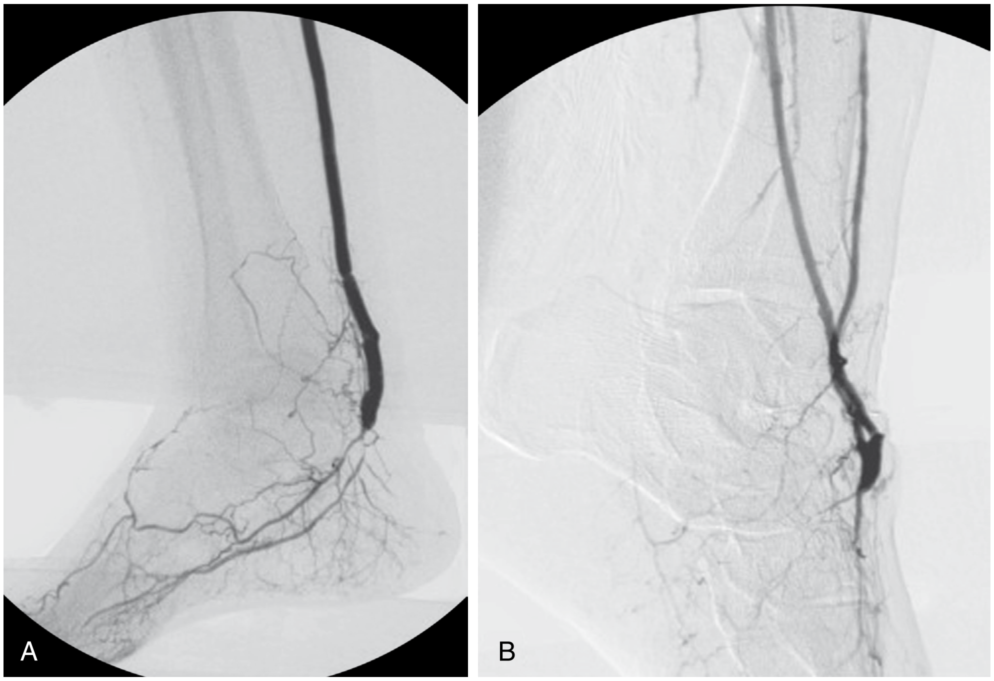

FIGURE 103.16 Detailed diagnostic arteriography with fixed imaging, proper timing, and appropriate catheter placement almost always identifies suitable target arteries. Each of the patients depicted had popliteal artery occlusion, extensive trifurcation, and long-segment tibial disease, but diagnostic studies identified suitable target arteries in the foot. (A) Completion arteriogram after inframalleolar posterior tibial bypass in a patient with diabetes and forefoot gangrene. Despite a small-caliber outflow vessel, the bypass remains patent, and the ischemic foot ulcers healed and have not recurred at 2 years. (B) Completion arteriogram after bypass to a diseased dorsal pedal artery. Despite poor outflow and diseased arch and pedal vessels, the graft remains patent at 1 year. This patient with diabetes healed and ambulates with a transmetatarsal amputation. (From Mills JL. Infrainguinal disease: surgical treatment. In: Sidawy AN, Perler BA, eds. *Rutherford's Vascular Surgery and Endovascular Therapy.* 9th ed. Philadelphia: Elsevier; 2019:1438-1462.)

recurrent atherosclerotic disease. These should generally only be treated for high-grade restenosis or whenever the patient has return of symptoms or a nonhealing wound. The rate of limb salvage in patients after graft failure is poor, with only a 50% ± 5% limb salvage rate 2 years after graft failure.[182]

ENDOVASCULAR TECHNIQUES

Principles of endovascular intervention include arterial access; the selection of sheaths, catheters, and wires to cross stenoses and occlusions; and ultimately, the treatment of the lesion.

Arterial access is achieved using a combination of anatomic landmarks, both palpable and fluoroscopic; palpation of the arterial pulse; and ultrasound guidance. Because the majority of complications resulting from endovascular interventions are access related, careful site selection and attention to technique in gaining access are imperative. Retrograde CFA access is commonly used in the treatment of lower extremity PAD because it can be used to address aortic and ipsilateral common iliac artery (CIA) lesions, as well as contralateral EIA and infrainguinal lesions, when the sheath is advanced up and over the aortic bifurcation. Antegrade access of the CFA may also be used in the treatment of infrainguinal lesions in the setting of a hostile contralateral CFA or iliac artery, presence of an inflow bypass, or challenging body habitus, without an increase in access site complications.[183] Because up to 20% of antegrade attempts to recanalize infrainguinal chronic total occlusions (CTOs) may fail, retrograde access of a tibial or pedal vessel, often in combination with antegrade access, may have success in crossing the lesion owing to more favorable morphology of the distal plaque cap.[184] Alternative access sites also include the brachial, radial, and popliteal arteries.[185]

After access is obtained, diagnostic angiography is performed to localize the lesions suspected from the information gathered in the preintervention physical exam, noninvasive studies, and cross-sectional imaging, if available. A sheath of sufficient length is advanced and positioned proximal to the lesion to provide stability. The inner diameter of the sheath is measured in French (Fr), with 1 Fr equal to 0.33 mm or 0.013 inches. It may become necessary to up-size the sheath to a larger French to accommodate the passage of balloons, stents, or other devices.

Once the sheath is in place, systemic anticoagulation is usually administered, and a combination of wires and catheters is used to traverse the lesion or lesions. Wires have variable lengths, diameters, shapes, weights, and stiffness. Although 180-cm wires may be sufficient to address lesions in the iliac and proximal SFA or lesions approached from an antegrade femoral access, depending on the distance from the site of skin entry distal to the target lesion, longer exchange-length 260- or 300-cm wires are often needed to treat infrageniculate disease from an up-and-over approach. Diameters of wires are measured in thousandths of an inch. Larger 0.035-inch wires are used in the treatment of more proximal aortoiliac and femoral lesions, whereas 0.018 and

0.014 wires are frequently used for tibial interventions. Wires have various shapes, as defined by the tip, including straight, angled, or preformed shapes, such as J-tip wires. The wire tip is generally floppier than the rest of the wire to minimize iatrogenic injury to the vessel, and the shape aids in the ability to steer the wire and select the target vessel. Wire material is also another factor to be considered. Hydrophilic wires are slippery when wet and provide less resistance than nonhydrophilic wires; however, these wires become sticky when dry and may require the use of a torque device to aid in steering. Wires are supported and directed by catheters, which also come in various shapes and lengths and are selected for use based on the anatomy encountered. Flush catheters have multiple side holes and are used for injection of contrast into high-flow vessels, whereas selective end-hole catheters have various configurations to allow for selection of the vessel of interest.

Ideally, the wire is maintained in the true lumen of the artery, and the stenosis or occlusion is crossed. Another technique for CTO lesions is subintimal angioplasty, a controlled arterial dissection used to traverse an occlusion through the subintimal plane. A loop is created using a hydrophilic guidewire just proximal to the occlusion. Because the subintimal plane is the path of least resistance, the loop can often be advanced into this space with the support of a catheter until it is beyond the lesion. At this point, the true lumen of the distal artery must be reentered. Once the true lumen is reentered, the wire should easily advance without resistance, and blood can be aspirated from the catheter. Entrance into the true lumen should be confirmed with a gentle contrast injection. In cases where the true lumen cannot be reentered, devices using IVUS or fluoroscopic guidance are available to improve success rates in achieving true lumen reentry.[186] A review of the literature on subintimal angioplasty for the treatment of femoropopliteal lesions reported technical success rates between 80% and 90%, 1-year patency rates ranging from 56% to 70%, and limb salvage rates of 73% at 5 years.[187] However, because of the lack of RCTs, there is insufficient evidence to support the use of subintimal angioplasty over other techniques.[188] In addition to standard wires and catheters, several devices have been developed to facilitate the crossing of more challenging lesions, including catheters capable of plaque microdissection, bidirectional spinning, and catheter tip deflection,[189] as well as wires with rotating tips.

After the lesion has been successfully crossed, the goal is to restore luminal patency. For complex lesions, IVUS is a useful imaging adjunct to gain detail on the luminal diameter and plaque characteristics. Balloon angioplasty, with or without stenting, is the mainstay of treatment. Angioplasty balloons are available in a wide variety of diameters and lengths and should be sized based on the diameter of the vessel so as to dilate the lesion while avoiding vessel rupture. During insufflation, a waist on the balloon confirms lesion location and resolves with successful dilation. Balloon angioplasty fractures the plaque, enlarging the flow lumen, but risks creating a focal dissection.

Specialized balloons have been developed for the treatment of more complicated lesions. Cutting balloons with longitudinally oriented microtomes can be used to create controlled cuts in fibrotic lesions to allow for subsequent angioplasty with larger balloons. Drug-coated balloons deliver antiproliferative medications to the vessel wall with the goal of preventing restenosis. Although treatment with drug-coated balloons has been shown to be associated with improved rates of primary vessel patency and reduced target lesion revascularization, there is no evidence of improved rates of amputation or change in ABI comparted with uncoated balloon angioplasty.[190,191]

Some have adopted a provisional stent strategy, reserving stents for residual stenosis, dissection, or other complications after plain balloon angioplasty. However, for iliac lesions, primary stenting has demonstrated improved outcomes compared with angioplasty alone, with improved 4-year primary patency rates in patients with claudication (77% vs. 68%) and CLTI (67% vs. 55%).[192] Primary stenting of iliac lesions has also been shown to be associated with lower rates of distal embolization.[193]

In femoropopliteal occlusive disease, stenting and angioplasty have been shown to have no difference in 5-year primary patency (angioplasty 36% ± 3% vs. 41% ± 4% for stenting; $p < 0.001$); however, stenting was shown to have improved outcomes in patients with more severe patterns of disease (TASC C and D lesions), with primary patency rates of 34% ± 6% versus 12% ± 9% ($p < 0.05$).[194] Immediate technical success is higher with stenting in the infrapopliteal segment, but no clear differences in short-term patency have been demonstrated versus angioplasty alone.[195] However, a recent retrospective study using data from the VQI registry reported improved 3-year amputation-free survival in patients treated with stenting (78.1% vs. 69.5% with angioplasty, $p = 0.001$).

Stents may be balloon expandable (BE) or self-expanding (SE) and can be covered or uncovered. BE stents are mounted on a balloon, allowing for precise deployment. BE stents are sized to the artery but can be dilated beyond the reported diameter with consequent shortening. These stents are more rigid with higher radial force, making them suited for short, eccentric, calcified lesions, such as the proximal CIA. SE stents are more flexible, making them more appropriate for mobile or tortuous vessels, such as the EIA and SFA. SE stents cannot be postdilated past the nominal diameter, so they should be oversized by 1 to 3 mm and postdilated after deployment to achieve maximal stent expansion. Uncovered stents have the advantage of preserving flow through side branches, whereas covered stents (stent grafts) may be used to prevent or treat vessel rupture or embolic lesions. Drug-eluting stents have the advantage of antiproliferative medication, which may increase patency compared with bare-metal stents.[196]

The Covered Versus Balloon Expandable Stent Trial (COBEST) demonstrated improved short- and long-term patency with covered stents compared with bare-metal stents in the treatment of AIOD, without significant difference in the rate of major limb amputations.[197] Covered stents for the treatment of long (≥20-cm) femoropopliteal lesions have shown improved patency rates compared with bare-metal stents[198]; however, among patients requiring reintervention for a failed SFA stent, patients with covered stents are more likely to present with ALI than patients with bare-metal stents.[199]

Atherectomy devices (orbital and laser) are designed to debulk lesions and increase the lumen size before definitive treatment with angioplasty and/or stent. These devices are widely used, but high-level data on long-term patency and limb outcomes compared with numerous alternatives are still lacking. Intravascular lithotripsy is a newer technology for the treatment of calcified lesions to fracture calcifications and reduce the diameter stenosis percentage before angioplasty or stenting; however, further studies are needed to evaluate its efficacy.[200]

Upon completion of the endovascular intervention, the sheath is removed, and the arterial access site must be controlled. Manual compression at the site of access is effective, and as a guideline, 5 minutes of pressure is applied per each French size (e.g., 25 minutes for a 5-Fr sheath). There are various vascular closure devices designed for arteriotomy closure, including suture, collagen plug, and metal clip–based devices. Similar rates of complication, safety and efficacy, and outcomes have been reported in comparing vascular closure devices to manual compression in femoral artery access.[201] Closure devices are associated with reduced time to hemostasis and ambulation compared with extrinsic compression[201,202]; however, it is important to understand the device mechanism and limitations to avoid potential device closure–related complications, such as bleeding, thrombosis, dissection, or stenosis.

Determinants of outcome of endovascular intervention depend on multiple factors, with worse outcomes reported for smaller and more distal lesions, longer lesions, total occlusions, multifocal and multilevel disease, poor distal runoff, and recurrent stenoses.[137,203–210] Female sex, comorbid conditions of DM and ESRD, and patients presenting with CLTI also have been shown to have less favorable outcomes with endovascular interventions.[135,137,211–213] However, endovascular interventions may be the preferred choice in older, high-risk patients with shorter life expectancies. Such interventions may be sufficient to heal wounds and prevent amputation in patients who would be unable to derive the benefit of longer patency with a bypass graft.

Complications

The most common complications associated with endovascular revascularization are related to the access site, including bleeding, hematoma, pseudoaneurysm, AVF, and access site stenosis or occlusion. In a retrospective review of over 45,000 patients undergoing infrainguinal peripheral vascular interventions via femoral arterial access, there was a 2.8% reported rate of hematoma, 0.4% of which required intervention, and a 0.3% rate of access site stenosis or occlusion.[183] Additionally, rates of arterial access pseudoaneurysm have been reported to be approximately 1%.[214,215] Risk factors identified to be associated with access site complications include advanced age, female sex, anticoagulant and antiplatelet use, COPD, CHF, ESRD, uncontrolled HTN, emergent intervention, larger sheath size, procedures >45 minutes, and tibial interventions.[214–217] Ultrasound guidance has been demonstrated to be associated with less frequent access site complications (4% vs. 7%, $p = 0.02$)[214] and was protective of hematoma, particularly in patients >80 years, obese patients, and sheath size >6 Fr.[218]

The use of contrast during angiography also confers risk of allergic reaction and contrast-induced renal injury. Contrast media reactions are related to histamine release and can range in severity from urticaria to anaphylaxis. Premedication with steroids and diphenhydramine can be used to decrease the risk of contrast-mediated allergic reactions. Contrast-induced nephropathy (CIN) has been reported to be 9% among patients undergoing peripheral angiography but is increased in patients with preexisting renal insufficiency.[219] To mitigate this risk, contrast can be diluted, or CO_2 arteriography can be employed; however, because of the reduced resolution, CO_2 may not provide adequate image quality to evaluate the vessels distal to the knee.[220]

Other complications of endovascular intervention include dissection, embolization, limb ischemia, and arterial rupture. Dissection can result from overdistention of a heavily calcified lesion and has been reported to occur in up to 7% of cases after balloon angioplasty.[221] The area of dissection can be identified on angiogram as a flap with contrast visualized on both sides. Extended, low-pressure balloon angioplasty can be performed to appose the dissection flap to the arterial wall; however, if the dissection is flow limiting, stenting should be performed. Distal embolization can be treated with aspiration or mechanical thrombectomy, but if unsuccessful, open surgical embolectomy or bypass may be required to restore distal perfusion. Severe pain is a sign of ALI or vessel rupture. In the case of vessel rupture, hemorrhage can be controlled temporarily using balloon occlusion, and a covered stent can be deployed across the area of perforation.

POST-REVASCULARIZATION SURVEILLANCE

Because of the chronic and progressive nature of PAD, regular follow-up is necessary and is an important component of providing comprehensive care to maximize patient outcomes. Structured surveillance is intended to identify threatened interventions before actual failure and to guide appropriate and timely reintervention. This longitudinal follow-up allows for evaluation of the revascularization, helps to ensure adequate medical management of comorbid conditions, and may improve patency and amputation-free survival after revascularization.[222] A general guideline after open surgical revascularization includes early postoperative assessment within 4 weeks of intervention and then at 3-, 6- and 12-month intervals after the operation. Thereafter, surveillance can be continued every 6 to 12 months.[223]

Surveillance has been especially well established for autologous vein grafts, for which identification and treatment of restenosis have benefit in prolonging graft patency and avoiding thrombosis of valuable vein conduit.[223,224] Duplex ultrasound has added utility over ABI assessment alone. To fully evaluate the bypass, the native inflow and outflow, proximal and distal anastomoses, and multiple intervals along the entire length of the graft are examined. Established criteria based on PSV, velocity ratio, low-flow velocity, and changes in ABI stratify the risk of thrombosis of infrainguinal vein grafts. Grafts are at high risk for thrombosis when any of the following are identified: PSV >300 cm/s and a PSV ratio >3.5 at the site of the stenosis, globally low peak systolic graft flow velocity <45 cm/s, or a drop in the ABI >0.15.[224,225] Any of these findings should prompt consideration for DSA and reintervention on the culprit lesion to prevent graft thrombosis (Fig. 103.17).

The most common cause of vein graft failure (75%–80%) in the first 3 to 8 postoperative months is an intrinsic vein graft stenosis resulting from neointimal hyperplasia. These lesions can be detected and monitored for progression by serial duplex surveillance. After 18 to 24 months, the de novo vein graft stenosis rate markedly declines, so in the absence of recurrent symptoms, annual surveillance is recommended. After prosthetic lower extremity bypass, surveillance does not reliably detect correctable lesions that precede graft failure, as it does in vein bypass grafts, and specific duplex criteria have not been established to accurately identify threatened prosthetic grafts. Surveillance may predict graft thrombosis when midgraft velocities are found to be <45 cm/s; however, no specific recommendations exist regarding the surveillance of or criteria for reintervention for prosthetic grafts.[69]

After endovascular revascularization, arterial restenosis frequently occurs through several mechanisms, including neointimal hyperplasia, constrictive arterial remodeling, and recurrent atherosclerotic disease. Velocity thresholds and criteria predictive of progression of stenosis that are sufficiently accurate to recommend reintervention after angioplasty, atherectomy, and stenting have not been established. Routine imaging with duplex ultrasound after endovascular intervention has not been demonstrated to improve clinical outcomes; however, there are subgroups of patients who may benefit from close surveillance and early reintervention. Patients with a

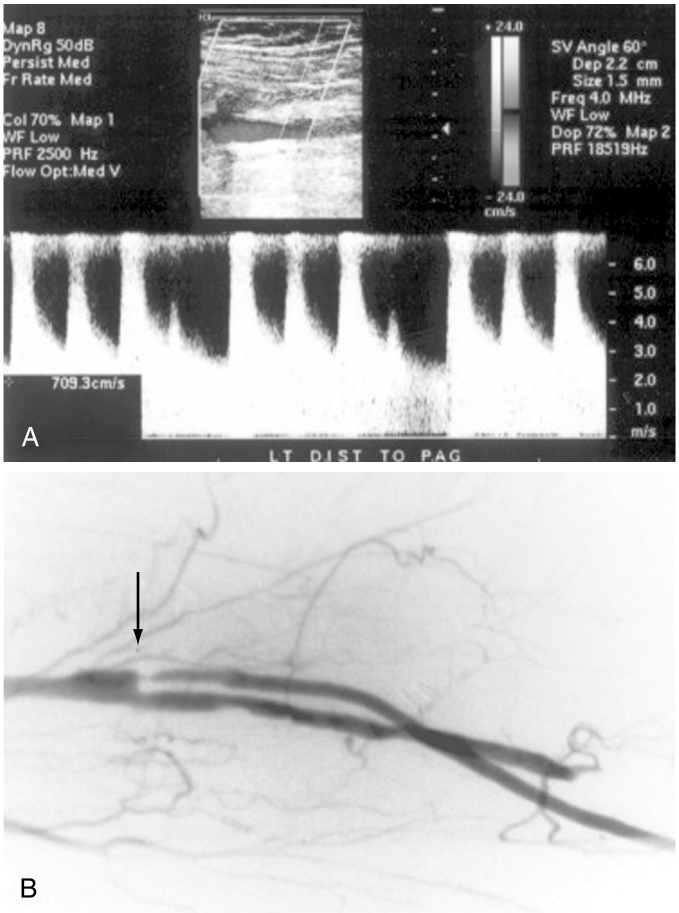

FIGURE 103.17 Duplex surveillance identified a critical vein graft stenosis in the proximal aspect of a femoropopliteal vein graft. (A) Marked spectral broadening and pronounced elevation of both the peak systolic and end-diastolic velocities are diagnostic of a high-grade vein graft stenosis. (B) A focal, severe proximal graft stenosis *(arrow)* was confirmed by arteriography and treated with a short interposition vein graft harvested from the upper extremity. (From Mills JL. Infrainguinal disease: surgical treatment. In: Sidawy AN, Perler BA, eds. *Rutherford's Vascular Surgery and Endovascular Therapy*. 9th ed. Philadelphia: Elsevier; 2019:1438-1462.)

history of multiple failed endovascular or open interventions, patients who present with severe ischemia or have unresolved tissue loss, and patients prone to failure of revascularization as a result of poor runoff or long target vessel occlusions should be considered for interval arterial duplex surveillance.[69] The SVS guidelines suggest continued clinical follow-up at 3 months and then subsequently at 6-month intervals to parallel the open surgical bypass recommendation. Further imaging and subsequent reintervention are generally only required in the setting of recurrent symptoms or failure of wound healing.[224]

ASSESSMENT OF OUTCOMES

Longitudinal assessments of vascular interventions have focused on end points of patency (primary, primary assisted, and secondary), hemodynamic success (based on ABI or toe pressure), limb salvage (lack of major amputation), and mortality. Anatomic outcomes have been used to define treatment success in many device trials: the presence or absence of restenosis, target lesion revascularization, and target vessel revascularization. Although these outcomes are important, they provide little meaningful patient-centered data for shared decision-making. In a study of 1012 patients in the Vascular Study Group of Northern New England database, it was found that 10% of patients with a patent infrainguinal bypass graft met criteria for the composite end point of clinical failure: major amputation, persistent rest pain, or tissue loss.[226]

To address this issue, the SVS published Objective Performance Goals to standardize the evaluation of new endovascular therapies and permit a suitable comparison to surgical bypass.[227] Based on evidence from three large RCTs for endovascular therapy and a surgical control arm, the following end points as safety and efficacy measures were recommended: MALE, MACE, major limb (proximal to ankle) amputation, amputation-free survival, and death. MALE is divided into major (new bypass graft or significant revision/jump graft, graft thrombectomy, or thrombolysis for graft occlusion) and minor (angioplasty or stenting for stenosis or focal patch angioplasty). Additionally, there has been an expansion of patient-centered functional outcomes after revascularization for CLTI, including relief of ischemic pain, complete healing of any index wounds, wound-healing time, wound recurrence rates, resumption or maintenance of ambulation, and independent living status. An older study of 112 consecutive patients 5 to 7 years after infrainguinal bypass for limb salvage found that only 26% of patients experienced limb loss; however, less than 15% of the patients had an ideal outcome as defined by the presence of the following criteria: patent graft, healed wound, no need for reintervention, continued ambulation, and independent living status.[228] This emphasizes that although timely and appropriate revascularization for CLTI offers clinically important outcomes, interventions are not curative and may not provide ideal patient-centered, functional outcomes.

Patient quality of life is another important consideration; several studies have demonstrated that patients with CLTI have impaired health-related quality of life (HRQoL).[229,230] Among CLTI patients enrolled in the BEST-CLI trial, advanced WIfI stage was independently associated with a reduced HRQoL and found to be related to mental, rather than physical, health.[231] A recent prospective study of 190 patients planned for endovascular or open revascularization of femoropopliteal occlusive disease demonstrated that although CLTI profoundly affected HRQoL, as measured using the Vascular Quality of Life Questionnaire, significant improvement was observed after revascularization.[5]

ACUTE LIMB ISCHEMIA

ALI is a surgical emergency that results from abrupt interruption of blood flow and downstream hypoperfusion of the tissue. Irreversible muscle and nerve injury can occur after 6 hours of severe arterial insufficiency.[128] There are approximately 1.5 cases of ALI per 10,000 persons per year, and it is associated with high rates of morbidity and mortality.[232] Perioperative mortality rates of 20% to 40% and limb loss rates of 12% to 50% have been reported in cases of lower extremity ALI.[233,234]

Presentation and Evaluation

The clinical characteristics of ALI can be summarized with the “six Ps”: pain, pulselessness, poikilothermia (coolness), paresthesia, pallor, and paralysis. The severity of the clinical presentation varies based on the duration of the arterial occlusion, the location of the occlusion, and the extent of collateral circulation. ALI is graded using the Rutherford Classification based on the neurologic

TABLE 103.4 Rutherford Classification of Acute Limb Ischemia

		FINDINGS		DOPPLER SIGNALS	
CATEGORY	DESCRIPTION/ PROGNOSIS	SENSORY LOSS	MUSCLE WEAKNESS	ARTERIAL	VENOUS
I. Viable	Not immediately threatened	None	None	Audible	Audible
II. Threatened					
a. Marginally	Salvageable if promptly treated	Minimal (toes)/none	None	Absent	Audible
b. Immediately	Salvageable with immediate revascularization	More than toes, associated rest pain	Mild, moderate	Absent	Audible
III. Irreversible	Major tissue loss or permanent neurologic damage	Profound, anesthetic	Profound, paralysis (rigors)	Absent	Absent

Modified from Rutherford RB, Baker JD, Ernst C, et al. Recommended standards for reports dealing with lower extremity ischemia: revised version. *J Vasc Surg.* 1997;2(3):517-538.

and vascular exam of the affected limb and is used to stratify urgency of intervention (Table 103.4).

Physical exam is used to determine the severity of ALI and level of occlusion and is one of the most important ways to determine appropriate management. The affected limb is cool and pale, with a varying degree of sensory and motor loss (Fig. 103.18). The temperature level (border of coolness and warmth) and presence of proximal pulses suggest the location of the occluded vessel. Continuous-wave Doppler evaluation of peripheral signals (i.e., multiphasic versus monophasic versus absent signals in comparison to the contralateral limb) is also useful to assess the level of arterial occlusion and degree of arterial insufficiency.

Etiology: Embolism Versus Thrombosis

ALI presents with similar symptoms regardless of cause; however, management strategies will differ based on the etiology of the arterial occlusion. The most common causes of ALI are embolism and thrombosis. However, other causes, including traumatic injury, aortic dissection, and hemodynamic states (e.g., low flow as a result of shock or use of medications such as vasopressors), may be operative. An embolus is organized intravascular material that originates in one location and travels to another, where it causes an occlusion. A thrombosis is a local occlusion in an already injured or diseased artery. Pertinent history to discover the etiology includes prior embolic episodes, history of PAD, recent MI, arrhythmias, valvular heart disease, aneurysmal disease, dissection, prior vascular interventions, and hypercoagulable states.

Acute onset of ischemic pain in a patient without preexisting PAD and normal vascular exam of the contralateral limb suggests an embolic event. Approximately 80% of emboli originate in the heart,[235]and 0.5% of all adult patients with atrial fibrillation will have a noncerebrovascular embolic event.[236] The thromboembolic risk for prosthetic heart valves, whether bioprosthetic or mechanical with oral anticoagulation, ranges from 0.6% to 2.3% per patient-year. Mitral compared with aortic prosthetic valves have a two- to three-times-greater risk of embolism. It is also important to evaluate for paradoxical emboli, which are emboli from a deep venous thrombosis that travels through an intracardiac septal defect to the arterial circulation. Noncardiac sources of embolization include aortic, femoral, and popliteal aneurysms. Microemboli are smaller and usually consist of platelet aggregates and cholesterol, occurring from atherosclerotic plaque rupture.

Emboli typically lodge at arterial bifurcations where there is a diameter change in the vessel that prevents further travel (Fig. 103.19). However, it is also possible for concomitant microemboli to cause occlusion in the distalmost arteries, which creates multilevel arterial occlusions requiring intervention. Microembolism can occur alone, and the embolic material lodges in the digits, causing "blue toe syndrome," petechiae, and/or splinter hemorrhages.

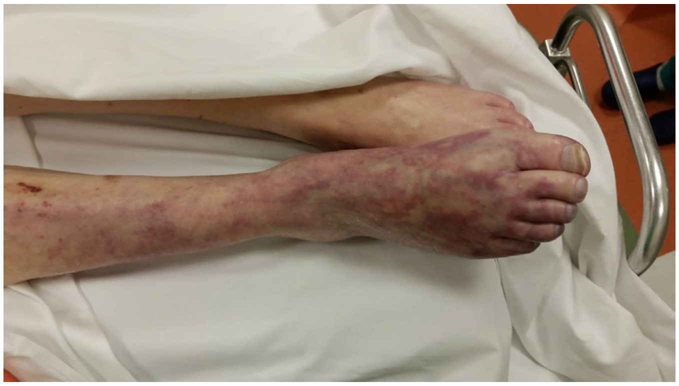

FIGURE 103.18 Acute limb ischemia of right lower limb (Rutherford IIb). (From Ferrer C, Cannizzaro GA, Borlizzi A, Caruso C, Giudice R. Acute ischemia of the upper and lower limbs: tailoring the treatment to the underlying etiology. *Semin Vasc Surg.* 2023;36(2):211-223. doi:10.1053/j.semvascsurg.2023.04.006)

In contrast, patients with a history of PAD are more likely to experience an in situ thrombosis of a diseased vessel. Arterial aneurysms, hypercoagulable states, and phlegmasia cerulea dolens can also lead to lower extremity arterial thrombosis. In patients with an acute-on-chronic process, the established collateral circulation may limit the severity of ischemia, but definitive restoration of tissue perfusion may be more technically challenging because of the underlying disease patterns.

Management

The goals of management of ALI include immediate anticoagulation and restoration of arterial circulation using open or endovascular techniques, assessment of ischemic injury to tissue, and identification and treatment of the thromboembolic source.

As soon as ALI is suspected, anticoagulation (75–100 units per kilogram intravenous heparin) should be administered as a bolus to prevent propagation of the thrombus and maintain patency of collateral vessels. A heparin infusion at 15 to 18 units per kilogram per minute should be continued until definitive treatment occurs and transitioning to oral anticoagulants is deemed appropriate. Direct thrombin inhibitors, lepirudin (renal metabolism), or argatroban (hepatic metabolism) can be used in patients with a contraindication to heparin.

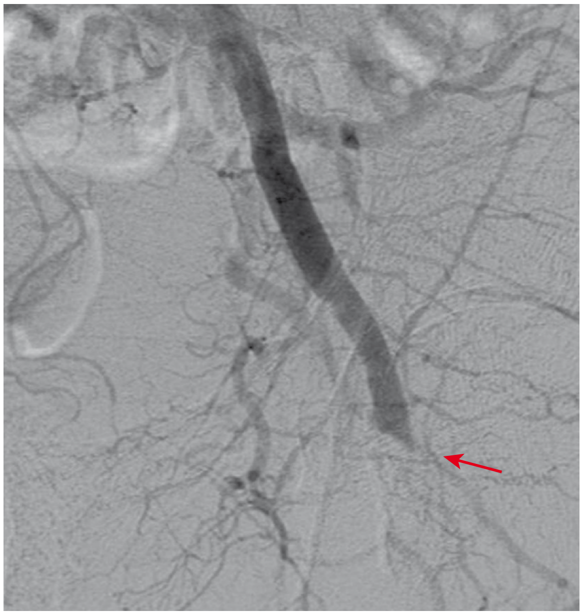

FIGURE 103.19 Angiogram showing an abrupt cutoff of the left common femoral artery consistent with the appearance of an embolus *(arrow)*.

There are three primary interventional approaches for revascularization: open surgical thrombectomy; hybrid approaches; and percutaneous endovascular therapy, including catheter-directed thrombolysis (CDT), pharmaco mechanical, and aspiration thrombectomy. There are no high-quality data demonstrating superiority of any one technique compared with another. When selecting the approach, severity of ischemia at presentation, time to reperfusion, chance of tissue recovery, underlying etiology, location of occlusion, procedural risks, and comorbid conditions are considered.

In purely embolic events, successful extraction of the embolus by endovascular or open techniques may reveal a widely patent arterial system with no need for further intervention. More commonly, thrombosis of an already stenotic atherosclerotic lesion is observed. The prospective population-based Oxford Vascular Study observed that 42% of patients presenting with ALI had preexisting PAD, and 40% had known atherosclerotic risk factors.[237] In cases of thrombosis, once the thrombus is removed, the underlying stenosis or occlusion must be treated to minimize the risk of re-thrombosis. Discrete atherosclerotic lesions may be treated with balloon angioplasty or open surgical endarterectomy with patch angioplasty, whereas more extensive lesions may require stenting or bypass.

An endovascular approach should be contemplated in patients with a marginally threatened limb (Rutherford I and IIa), in those at medically high risk for open surgery, and in the setting of a thrombotic occlusion. Patients with distal emboli, as observed in patients with a normal femoral pulse but absent distal pulses, may benefit from an initial angiogram and CDT/mechanical thrombectomy. This strategy may be more effective in establishing reperfusion of smaller distal vessels and elucidating concomitant atherosclerotic lesions, which may be treated endovascularly. In the case of thromboembolism associated with a popliteal artery aneurysm, establishment of distal peripheral circulation using thrombolysis is the recommended strategy in the absence of immediate limb threat.[238] The disadvantage of CDT is the relatively longer time periods required to achieve tissue reperfusion and risk of potential bleeding complications. Percutaneous mechanical thrombectomy techniques were introduced to address these shortcomings, decreasing the need for prolonged infusion times and reducing the need for multiple procedures required for successful thrombolysis. Absolute contraindications to pharmacologic thrombolysis include active bleeding, stroke, or neurosurgical procedure within 3 months; malignant intracranial neoplasm; history of hemorrhagic stroke; or recent gastrointestinal bleed. Relative contraindications include severe HTN, central nervous system tumors or known intracranial pathology, trauma, and major surgery within 3 weeks.

Open embolectomy, using balloon-tipped Fogarty catheters, should be considered in patients with an immediately threatened limb (Rutherford IIb) because of the ease and speed of establishing reperfusion and in patients with a contraindication to fibrinolytic therapy. Ideally, these cases are performed in a hybrid operating room, which allows for use of adjunctive endovascular techniques and completion angiography. An open femoral embolectomy is indicated in patients with an absent or water-hammer ipsilateral femoral pulse and normal contralateral femoral pulse, whereas the absence of both femoral pulses suggests an aortic thrombus requiring bilateral femoral embolectomies.

In patients with irreversible ischemia (Rutherford III) with complete loss of motor and sensory function, inaudible arterial and venous Doppler signals, and presence of livedo reticularis, revascularization may cause life-threatening physiologic changes with little chance of functional limb salvage. A primary amputation in this setting is preferable to avoid multiple organ failure and death.

Despite successful revascularization, tissue damage may have occurred pending the severity and duration of ischemia time. Viable-appearing tissue is still threatened, and limb loss may occur from development of acute compartment syndrome as previously ischemic tissue swells within the confined fascial space of the calf. Four-compartment fasciotomies performed through medial and lateral lower limb incisions should be performed prophylactically in patients presenting with Rutherford IIA ischemia (Fig. 103.20). In patients with shorter-duration or less severe ischemia, it is acceptable to perform frequent serial exams to assess for reperfusion injury and compartment syndrome in the postrevascularization period. Signs of evolving compartment syndrome include tense compartments, pain with passive motion, decreased sensation (specifically at the dorsal first webspace of the foot), and motor weakness. If any of these clinical findings are present, immediate four-compartment release must be performed to avoid limb loss.

Postoperative management requires hemodynamic monitoring, fluid resuscitation and correction of acidosis and electrolyte imbalance from release of potassium and hydrogen ions from damaged tissue cells, and serial neurovascular exams. Accepting some amount of hematoma at the surgical sites or blood loss from open fasciotomy sites is necessary because the risk of acute rethrombosis is as high as 30% and can be prevented with continued therapeutic anticoagulation.

Once the acute episode has been managed, workup to diagnose the underlying etiology should be continued if the source is still unclear. Electrocardiogram can identify cardiac dysrhythmias, and echocardiogram can identify cardiac wall motion abnormalities, vegetations, and intracardiac thrombus. CTA of the chest, abdomen, and pelvis can identify aortic atheroma, aneurysm, or primary aortic thrombus. Duplex ultrasound or CTA can identify lower extremity arterial lesions if the source is thought to be more distal. If workup remains negative, then additional diagnostics include venous duplex

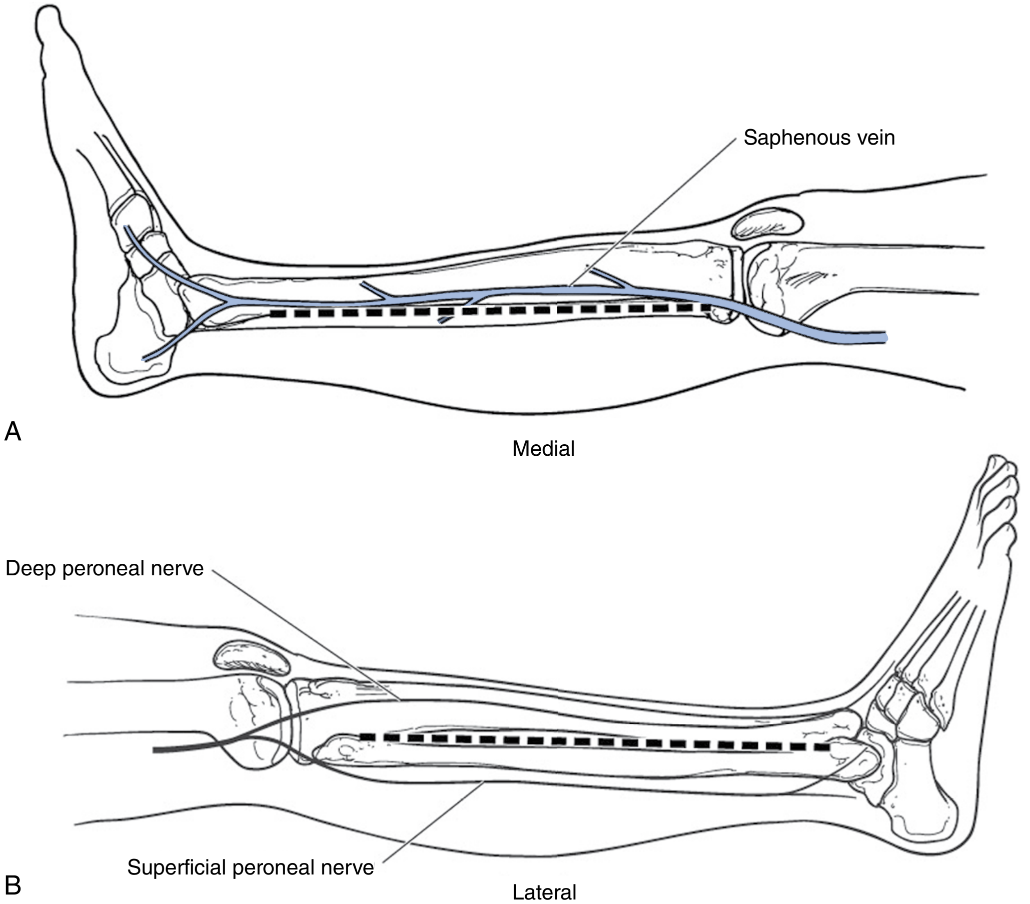

FIGURE 103.20 Lower extremity fasciotomy. (A) Both posterior compartments are released through a medial incision 2 to 3 cm posterior to the medial border of the tibia. The fascia of the superficial posterior compartment is incised, and the soleus muscle attachments to the tibia and interosseous membrane are divided to release the deep posterior compartment. (B) The anterior and lateral compartments are exposed through a longitudinal skin positioned between the anterior crest of the tibia and the fibula. Parallel incisions are used to release the fascia of the anterior and lateral compartments, which are separated by the intermuscular septum. Care is taken to avoid injury to the superficial peroneal nerve. (Adapted from Rasmussen TE, White JM. Upper and lower extremity fasciotomy. In: Chaikof EL, Cambria RP, eds. *Atlas of Vascular Surgery and Endovascular Therapy*. Philadelphia: Elsevier: 2014:619-623.)

ultrasound to evaluate for deep venous thrombosis and risk of paradoxical embolism and hypercoagulable workup (including primary blood disorders and cancer evaluation). Once the underlying etiology is identified, definitive treatment should be pursued expeditiously to avoid a recurrent event.

  The Ewing Amputation

INTRODUCTION

Surgical amputations have been an integral part of the treatment of various human ailments ever since the first evidence of medical practice emerged, even in prehistoric times. The application and evolution of these techniques have mirrored the recent, rapid advancements in medicine. Although the exact burden of disease is difficult to approximate, there are an estimated 2 million people in the United States living with limb loss and an additional 1 million people worldwide undergoing an amputation every year. The indications for amputation run the spectrum from diabetic infections and peripheral artery disease (PAD) to trauma and cancer, and the subsequent impact that limb loss can have on a patient's survival and quality of life cannot be understated. Thus, the role of the surgeon in the effective and appropriate application of amputations is paramount. The indications, techniques, complications, and outcomes of limb amputation will be discussed in the following sections.

INDICATIONS AND PERIOPERATIVE EVALUATION

Diabetes and Infection

Diabetes mellitus (DM) affects 10% of the US population with an increase in prevalence of about 200% from 1997–2015.[1] The number of Medicare fee-for-service beneficiaries with DM increased from 4.63 million to 6.87 million between the years 2000 and 2017.[2] Additionally, the proportion of patients who are male, older than 85, and who have multiple comorbidities has increased over time. Common complications of DM include retinopathy, nephropathy, and neuropathy, among many others. Diabetic neuropathic foot ulcers from chronic microvascular disease are prone to infection, and about 50% of those with ulcers also have concomitant PAD, which increases the risk of amputation.[1] Nontraumatic lower extremity amputation rates in patients with DM had initially decreased from 8.5 per 1000 people to 4.4 in 2009.[2] However, the amputation rates increased again to 4.8 in 2017. This increase may be from a rise in the number of minor amputations and the consequent decline in major amputations, mirroring a shift in the global management and selective application of amputations.

DM, along with renal failure and congestive heart disease, increases the risk of developing necrotizing soft tissue infections (NSTIs). Lower extremity NSTIs can be rapidly aggressive and require emergent surgical intervention whether in the form of debridement or amputation. Amputation may be appropriate for rapid source control in cases where there is extensive soft tissue damage, especially in the background of septic shock. With a major infection of the foot, especially with extensive plantar involvement, a two-stage procedure with initial guillotine amputation may aid in source control while providing the opportunity for maximal limb preservation. Indeed, some patients may require sequential debridement or amputation, during which time additional physiologic support and intravenous antibiotics can be administered until a juncture at which formal closure of the amputation can be performed.

Diabetes is also a major risk factor for atherosclerotic disease and the mortality from cardiovascular disease increases fourfold in diabetic patients.[1] In the EUCLID trial, patients with PAD and

DM had a lower extremity amputation rate of 5%, whereas nondiabetic PAD patients had an amputation rate of 1.5%. Even minor amputations are 4.6 times more likely to occur in patients with both diagnoses compared with patients with PAD alone.[3] Additionally, there was a twofold increased risk of minor amputations if baseline HbA1c was greater than 7%. Major adverse cardiovascular events occurred in 18% of diabetic patients with minor amputations and 16% with major amputations. All-cause mortality was also significant in these patients and occurred in 17% of patients with minor amputations and in 23% with major amputations. These findings highlight the crucial importance of perioperative care in improving the outcomes for these high-risk patients.

Peripheral Artery Disease

PAD in the lower extremities is caused by atherosclerotic plaque reducing the amount of oxygenated arterial flow, thus leading to ischemia. Many patients are asymptomatic and about 10% of patients with PAD have intermittent claudication (defined as pain, fatigue, or numbness in the lower extremities with activity that is relieved by rest).[1] Out of all patients with PAD and intermittent claudication, about 21% of them will have progression of disease over 5 years with an amputation rate of about 1%.[4] The prevalence of PAD has increased with the aging population, increasing obesity, and as a complication of DM.[3] Chronic limb-threatening ischemia (CLTI) is an advanced progression of PAD, which may lead to minor or major amputation if left untreated.

Acute Limb Ischemia

Acute limb ischemia (ALI) is caused by an arterial occlusion with associated symptoms that have been present for less than 2 weeks. Etiologies include embolism, thrombosis, or trauma. The Rutherford classification of ALI further stratifies the disease entity based on clinical examination as viable, threatened, or irreversible.[4] Irreversibly ischemic limbs with major tissue loss or permanent nerve damage with profound sensory/motor loss should be treated with primary extremity amputation. Revascularization of a nonviable extremity in rigor should be avoided because it could lead to multisystem organ failure and death. Primary amputation may also be the best option for patients with poor overall health whose disease presents with devastating tissue loss, especially when combined with nonambulatory status.

Determining the cause of ALI is of paramount importance and can guide therapeutic trajectory. Often, systemic anticoagulation should be considered and modalities that allow for titration and quick reversal should be given preferentially. Other diagnostic modalities could include an echocardiogram to identify embolic sources along with aortic cross-sectional imaging of the chest, abdomen, and pelvis. Determining the most appropriate level for amputation requires a thorough diagnostic approach and may include a full pulse examination with Doppler ultrasonography, computed tomographic angiography (CTA), arterial ultrasound, percutaneous arteriography, or magnetic resonance angiography. Time to therapy is crucial in preserving limb tissue and function, and, as such, CTA may be the fastest diagnostic tool to help guide the operative approach whether that may be an endovascular, open, or hybrid procedure. Four compartment fasciotomies of the lower extremity should always be considered after revascularization, especially if ischemia time is greater than 6 hours[4] (Table 104.1).

Chronic Limb Ischemia

CLTI is defined as arterial occlusive disease causing greater than 2 weeks of symptoms of rest pain or tissue loss with diagnostic study findings reciprocating arterial insufficiency. Although data are limited, less than 5% of patients with PAD progress to CLTI.[5] A recent systematic review summarized 13 studies and showed a major amputation rate of 22% if CLTI is left untreated.[5] In a study evaluating patients undergoing major lower limb amputation between 2000 and 2016 using the National Inpatient Sample, there has been an overall decrease in amputation rates.[6] During this same time frame, there has been an increase in endovascular intervention for arterial disease along with improvements in wound management that may be contributing to the downward trend.[6] Not surprisingly, chronic ischemia and infection remained the most common indications for amputation among this sample of hospital inpatients.

A study from Switzerland evaluating patients with CLTI from 2000–17 showed an increase in endovascular revascularization with a median of two revascularization procedures performed before amputation.[7] Among these patients with PAD, the 30-day mortality in below-knee amputation patients was 8.9% and above-knee amputation patients had a mortality rate of 27.7%.[7] With the significant mortality risk seen in this progressive disease process, the Society of Vascular Surgery (SVS) Guidelines Committee created the lower extremity threatened limb Wound Ischemia and foot Infection (WIfI) system.[8] The classification system has three factors that comprise the score: wound characteristics, degree of pedal perfusion, and extent of infection.[8] The WIfI system was not designed to be a clinical decision-making tool, but validation studies have shown worsening WIfI scores correlate with the risk of major amputation.[8] Additionally, using the WIfI score as a metric of goal-directed treatment may lead to improved clinical outcomes.

In establishing the degree of perfusion in CLTI patients, careful physical examination is crucial to evaluate the skin for any wounds, level of rest pain, and determining motor and sensation

TABLE 104.1 **Classification of Acute Limb ischemia**

CATEGORY	DESCRIPTION/PROGNOSIS	FINDINGS SENSORY LOSS	MUSCLE WEAKNESS	DOPPLER SIGNALS ARTERIAL VENOUS
Viable	Not immediately threatened	None	None	Audible Audible
Threatened				
a. Marginally	Salvageable if promptly treated	Minimal (toss) or none	None	Inaudible Audible
b. Immediately	Salvageable with immediate revascularization	More than toes associated with rest pain	Mild, moderate	Inaudible Audible
Irreversible	Major tissue loss permanent nerve damage inevitable	Profound, anesthetic	Profound paralysis(rigor)	Inaudible Inaudible

From Rutherford RB, Baker JD, Ernst C, et al. Recommended standards for reports dealing with lower extremity ischemia: revised version. *J Vasc Surg.* 1997;26:517-538.

in the extremity. Noninvasive measurements of ankle and toe pressures, arteriography, and transcutaneous oxygen measurements can help direct the level of amputation in order to maximize the chances of complete healing. Revascularization is also crucial in limb preservation along with meticulous wound care and infection control.

Trauma

Extremity trauma is the second most common indication for amputation, accounting for about 45% of all amputations.[9] Traumatic injuries may compromise vascular supply, orthopedic integrity, and soft tissue coverage leaving amputation as the only viable option. Both blunt and penetrating traumatic injury to the lower extremities has a high morbidity rate and an elevated amputation risk. A study examining penetrating lower extremity trauma from 2005–14 from the National Inpatient Sample found that patients with firearm injuries had higher rates of in-hospital major amputation and mortality compared with the nonfirearm group.[10] Furthermore, analysis of the National Trauma Data Bank found that amputations occurred more often for blunt traumatic lower extremity injuries (9.1%) compared with penetrating injuries (5.1%; $P = 0.05$).[10] Both of those findings suggest that the greater the degree of trauma to the extremity, the higher the amputation rate. In fact, trauma patients presenting with a vascular injury and concomitant orthopedic injury had about a sevenfold increased risk of amputation compared with those without orthopedic injury.[9]

Oncology

Modern cancer care is an intricate multidisciplinary orchestration that balances effective disease control with the morbidity of systemic therapy, surgery, and radiation to allow patients to live a longer and better quality of life after their diagnosis. Limb-sparing approaches are now, for the most part, standard of care when it comes to the management of locoregional disease. Malignancies that affect the extremities must be approached with this framework in mind, leaving amputation as an option in very select circumstances. For example, tumors that remain locoregionally bound but have failed multiple lines of multimodal therapy or attempts at less extreme resection may require amputation. Additionally, tumor characteristics such as proximity or involvement of crucial neurovascular structures may not be adequately treated with limb-sparing approaches. Finally, resection status plays a pivotal role in disease control, and the ability to ensure negative margins may necessitate amputation, especially in the case of distal digit involvement.

Melanoma

Melanoma stems from the aberrant transformation of pigment-producing cells and ranks as the fifth most common cancer diagnosis in the United States.[11] The treatment landscape has undergone drastic evolution, especially in the case of advanced and metastatic disease; however, the keystone of local management remains complete surgical resection. Traditionally, amputation has been applied in two clinical scenarios: the management of early-stage subungual and distal digit disease and in the management of extensive regional/in-transit disease confined to a limb.

Subungual melanoma comprises a relatively small fraction of cases, roughly 1% to 3%, and since the late 1900s management has focused on early distal digit amputation.[12] Consequent attempts at including additional regional control modalities such as digit amputation with isolated limb perfusion did not appear to bear clinical benefit.[13] Consequently, digit amputation has remained the standard procedure for this disease; however, recent investigations have begun to call this approach into question. Specifically, patients who undergo digit amputation, particularly of the thumb or first toe, can experience significant alterations in quality of life. Retrospective analysis has demonstrated that more limited, nonamputation resection may provide clinical equipoise.[14,15] Ongoing investigations including the Japanese Clinical Oncology Group Study 1602 may provide additional clarification once data maturation has occurred and takes into account the relatively shallow tissue plane available for digit-sparing approaches.[16] Given the importance of achieving margin control in melanoma along with some reports of worsened local recurrence rates with less-than amputation approaches, Mohs micrographic surgery for melanoma excisions of the digit has begun to gain traction as a possible alternative to traditional wide local excision or amputation.[17]

Further along the clinical spectrum, more advanced stage melanoma of the limb has also been considered for amputation including extensive hand and forelimb resections; however, this practice has likely become of mostly historical interest because the modern application of multimodal therapies has obviated such aggressive measures. Between the introduction of regional perfusion and immunotherapy, the management of locoregionally advanced or recurrent melanoma only requires amputation in the most extreme cases, including those of intractable pain or sepsis source control.[18]

Sarcoma

Soft tissue sarcoma (STS) represents a heterogenous group of rare tumors with only an estimated 13,400 new cases reported in 2023.[11] Nearly half of STS will be limited to the extremities, and the surgical approach to this disease was traditionally centered around complete disease control through limb amputation. However, starting in the late 1970s, a shift toward limb preservation became more prevalent.[19] A landmark study in 1982 formed the basis for limb-sparing approaches to STS and found that there was no difference in survival for those patients undergoing nonamputation resection.[20] Most modern series estimate that STS necessitating amputation is limited to 5% to 10% of all cases, and those patients tend to have direct and extensive tumor involvement of major neurovascular structures or that the tumor size encompasses too much of the limb to allow for a functional or meaningful remnant.[21,22]

In summary, amputation for oncologic indications is becoming more rare; however, in highly select cases where limb salvage is not possible, amputation can provide not only palliation, but also long-term prognostic benefits.

TECHNICAL CONSIDERATIONS

Lower Extremity Amputations

Toe Amputation

The indications for toe amputation, the most frequently performed lower extremity amputation, include wet or dry gangrene, infected neuropathic ulceration, or osteomyelitis. Preoperative physical examination along with radiographic examination for osteomyelitis with x-rays or magnetic resonance imaging is critical. The operative plan should include resecting all nonviable skin, all bone involved by osteomyelitis, and closure of the wound if there is no gross purulence in the wound.

With infection confined to the distal phalanx or mid phalanx, the transected level should be through the proximal phalanx to healthy bone margins. Interphalangeal joint disarticulation should be avoided due to the avascular nature of cartilage potentially leading to persistent infection and impaired healing. If infection involves the proximal phalanx, then the metatarsophalangeal (MTP) joint should also be resected with a ray amputation (discussed later).

The location and orientation of the skin incision depends on the extent of the infection, but the most commonly used is a circular incision around the base of the toe with skin flaps usually shaped into a fishmouth to minimize dog-ear deformities at the corners of the closure. Other skin flap variations such as a side to side, dorsal base, or plantar base would be appropriate while making sure that the skin edges are approximated under no tension. Closure is accomplished using a monofilament permanent suture, such as 3-0 nylon suture on a cutting needle. Simple interrupted stitches may be used, but a vertical mattress stitch provides deep and superficial layer closure with good eversion of the dermal edges. A soft dressing with compression should be placed to help with hemostasis. Postoperative management should include either a front off-loading boot or non–weight-bearing status to prevent trauma to the amputation site (Fig. 104.1).[23]

Ray Amputation

A ray amputation may be used when there is a need to resect the MTP joint or the distal metatarsal bone has become involved with infection. Removing the MTP joint of the great toe affects gait stability and would require proper footwear with physical therapy.

A racket incision can be used if there is healthy tissue at the base of the toe. It is a circular incision at the base of the toe that is extended onto the dorsal aspect of the metatarsal bone more proximally. In general, an incision on the dorsal aspect of the foot is recommended for better healing compared with plantar surface incisions. Incision is deepened through muscles and tendon onto the metatarsal bone. Medial and lateral dissection around the metatarsal bone is carefully done to not injure the digital arteries or nerves. An oscillating electric saw can be used to transect the metatarsal bone to a healthy margin determined by either preoperative imaging or clinical examination.

The wound should be irrigated and hemostasis achieved. The skin flaps may be closed with vertical mattress monofilament permanent suture with a soft dressing and compressive wrap to help with hemostasis and to protect the wound closure. If gross infection is present, the wound may be left open to allow for further drainage and allow the wound to heal by secondary intention with proper wound care (Fig. 104.2).[23]

Transmetatarsal Amputation

Transmetatarsal amputation is indicated for patients with multiple toe infections up to the MTP joint or proximally on the distal metatarsal of the same foot. A healthy plantar skin flap is requisite for closure. Operative planning requires careful physical examination with imaging evaluation for osteomyelitis.

An incision is made on the dorsum of the foot from medial to lateral at the level of the mid-metatarsal shafts. The dissection deepens down to the metatarsal bones, and an electric saw is used to transect each metatarsal shaft about 5 mm proximal to the skin incision. The bones are then elevated and separated from the plantar tissue with preservation of as much of the plantar flap as possible. The tendons on the plantar flap need to be sharply excised with preservation of the muscle. The plantar flap is then rotated dorsally for closure and can be trimmed to allow for a tension-free approximation.

Irrigation and impeccable hemostasis are achieved with cautery or suture ligation. The deep layer is closed with 2-0 absorbable interrupted sutures, and the skin is brought together with monofilament permanent suture using an interrupted vertical mattress technique. Dressings need to fully protect the stump from any trauma, and the patient should be kept non–weight bearing until fully healed. Another option is a well-padded leg plaster cast for the lower leg to prevent trauma to the stump. Proper prosthetic shoes providing toe-off motion during ambulation allow for rehabilitation with minimal limitations (Fig. 104.3).

Lisfranc and Chopart Amputation

Although not as commonly performed as a below-knee amputation, proximal foot amputations may be warranted for limb salvage. The Lisfranc tarsometatarsal disarticulation uses a long plantar flap with disarticulation of the first, third, fourth, and fifth tarsometatarsal joints. The second metatarsal is transected 2 cm distal to the medial cuneiform. To avoid an equinovarus deformity, the base of the fifth metatarsal with the peroneus brevis is preserved. The Achilles tendon is released, and the plantar fascia is approximated to the fascia and periosteum on the dorsum of the foot with absorbable sutures. Interrupted vertical mattress sutures or skin staples are used for closure with a plaster cast to ensure that the talus is slightly dorsiflexed in relation to the tibia.

The Chopart amputation also uses a long plantar flap, but this amputation is performed through the talocalcaneonavicular

joint and the calcaneocuboid joint. The Achilles tendon should be released as well, and the extensor hallucis longus and extensor digitorum longus may be reattached. Patients who undergo this procedure require custom fitted orthotic shoes for ambulation.

Below-Knee Amputation

Below-knee amputation is indicated in patients with major infections of the foot, significant tissue loss, or inadequate arterial flow into the foot with no revascularization options. Below-knee amputation is not an option if the patient has a flexion contracture at the knee. There should also be enough viable anterior and posterior flap for coverage in the lower leg. An ankle-brachial index greater than 0.5 or angiographic evidence of patent iliac artery flow to a patent profunda artery even with an occluded superficial femoral artery is sufficient for healing. Ambulation rates with or without assistance have been seen in up to 65% of below-knee amputees.[24]

General anesthesia or spinal anesthesia are options with or without regional nerve block for postoperative pain control. A two-stage, below-knee amputation for the septic foot patient offers better outcomes with less stump infection compared with a one-stage approach. Those patients with a grossly infected foot should have a guillotine amputation as distal as possible to healthy tissue. Once the patient has stabilized, the below-knee amputation can be formalized.

The use of the long posterior flap relies on blood supply from the sural arteries, which originate proximal to the knee joint. Most patients requiring amputation due to PAD may have compromised tibial arteries, specifically the anterior tibial artery, which perfuses the soft tissue and skin of the anterior lower leg. Therefore, the long posterior flap technique offers better healing and recovery. In patients with inadequate posterior flap soft tissue, the sagittal flap or a skew flap could be used for closure. The sagittal technique uses equal length medial and lateral myocutaneous flaps to cover the tibia, whereas the skew technique uses equal anteromedial and posterolateral flaps (Fig. 104.4).

Posterior Flap

The tibia should be divided 12 to 15 cm distal to the tibial tuberosity. The circumference of the calf at the designated level of the tibia transection is measured, and two-thirds of that circumference will be the length of the anterior incision centered on the tibia. The posterior flap length is one-third of the circumference and is fashioned down toward the ankle making sure to angle the lateral and medial incisions toward the malleolus on each side. Cautery is used to deepen the incision through the fascia and muscles of the anterior and lateral compartments, and a periosteal elevator is used to mobilize the periosteum off the tibia and allow for a transection 2 cm proximal to the skin edge. An oscillating bone saw is used to transect the tibia and to bevel out the anterior sharp edge of the tibia stump. Next the fibula is dissected out and transected with a bone cutter about 2 cm proximal to the level of the tibial transection. A large amputation knife or cautery is then used to excise the muscle from the posterior aspect of the tibia and fibula. The vascular bundles should be suture ligated. The tibial and peroneal nerves are tied off with an absorbable suture and sharply excised as proximal as possible to allow for retraction. The muscle on the posterior flap can be debulked if needed with preservation of the gastrocnemius muscle and fascia. The wound is then irrigated and hemostasis achieved with avoidance of using any bone wax. The fascia of the posterior flap is approximated to the fascia anterior to the tibia with interrupted absorbable sutures. Interrupted deep dermal absorbable sutures are followed by either a stapled or a vertical mattress skin closure (Fig. 104.5).

Through-Knee Amputation

A through-knee amputation may be offered to patients who have enough compromised soft tissue in the lower leg where a below-knee amputation would be inadequate but in whom there is a reasonable rehabilitation potential. This technique may also allow for a better rate of ambulation compared with above-knee amputation. As originally described by Mazet, the distal femur is preserved with trimming of the condyles.[23] The anterior flap of the fishmouth incision is extended to the level of the tibial tuberosity with the posterior flap as the same length or slightly longer. The medial and lateral collateral ligaments are divided, and the patellar ligament length is preserved as it is divided from the tibial tuberosity. The knee capsule is excised and the cruciate ligaments divided. The popliteal artery and veins are suture ligated and the tibial and common peroneal nerves are tied with absorbable suture on tension before sharp transection, allowing for retraction. The lateral condyle and medial condyles are trimmed, and the posterior surface is squared with smoothing of the edges with a rasp or bone saw. The hamstring tendons are approximated to the patellar ligament while securing them to the cruciate ligaments. The fascia is finally closed with interrupted absorbable sutures and skin closed with staples or vertical mattress permanent sutures (Fig. 104.6).

Above-Knee Amputation

Above-knee amputation is indicated for patients who are bedbound or with severe tissue loss from either ischemia or infection not allowing for a below-knee amputation. The femur may be transected as proximal as needed for skin closure, but typically can be divided in the distal one-third portion. The incision is done using a fishmouth technique with anterior and posterior flaps with corners curving proximally. The posterior flap may be made about 1 to 2 cm longer if possible to avoid having the incision in a dependent position. The skin and muscle are incised with suture ligation of the femoral artery and vein. A periosteal elevator is used to clear the femur about 2 to 3 cm proximal to the skin incision where it is transected using an electric saw proximal to the corners of the incision. The sciatic nerve is put on tension, tied with absorbable suture, and sharply transected allowing it to retract. The wound is irrigated and hemostasis obtained. Muscle is then reapproximated with absorbable sutures over the femur bone. The anterior and posterior fascia is brought together with interrupted absorbable sutures, and skin is then closed with vertical mattress interrupted permanent sutures or deep dermal absorbable sutures and skin staples.

Hip Disarticulation

Hip disarticulation is highly morbid and only indicated in a very select population of patients including those with proximal malignancies requiring surgical resection. With the patient in a semilateral position, an anterior racket incision is extended from medial to the anterior superior iliac spine toward the pubic tubercle, and it is extended posteriorly distal to the ischial tuberosity and gluteal crease. The incision continues anteromedially to the greater trochanter and back to the start of the incision. The dissection is deepened down to the external oblique aponeurosis and deep fascia of the thigh with careful suture ligation of the femoral vessels. The femoral nerve is transected on tension and allowed to

retract. The sartorius muscle is divided at its origin, the iliopsoas is divided at its insertion site, and the pectineus is divided at its origin. The obturator neurovascular bundle is suture ligated. The gracilis and three adductor muscles are divided from the pubic rami. The posterior thigh muscles are transected at the ischial tuberosity, and all the muscles attached to the greater trochanter are divided. The ligaments of the hip joint and the capsule are resected. The posterior quadratus femoris is approximated to the anterior iliopsoas, and the lateral gluteus medius is approximated to the medial obturator externus. The gluteal fascia is then approximated to the inguinal ligament, and the skin is closed with deep dermal absorbable sutures and skin staples.

Upper Extremity Amputations

The majority of upper extremity amputations are due to trauma of the hand; however, other indications such as malignancy may be possible. Unlike the lower extremity amputation in which the primary goal often is adequate soft tissue coverage in order to fit into a prosthesis, the upper extremity amputation also has to be functional and cosmetically acceptable.

Digit Amputation

Depending on the level of injury or proximal margin needed, digit amputations involve preserving length as much as possible for functional recovery. A small rongeur is used to take the phalanx

bone back enough for the soft tissue to close. Tendons are put on tension and transected allowing them to retract. The digital nerves are dissected and sharply divided on slight tension to allow retraction without injury to the nerve. Nerves directly abutting the stump could lead to postoperative pain or neuromas. Soft tissue closure can be accomplished with permanent interrupted sutures, or small wounds can be allowed to heal by secondary intention.

Ray amputation of the finger to the metacarpal base usually involves a dorsal longitudinal incision as well as a palmar skin incision over the proximal phalanx or alternatively a racket incision may be applied.

Below-Elbow Amputation

Preserving as much tissue during a hand amputation is important for functional and possible prosthesis use. Wrist disarticulation involves the creation of a long palmar flap and short dorsal flap. Radial and ulnar arteries are suture ligated proximal to the wrist. The median, radial, and ulnar nerves are sharply divided on slight tension as are all of the tendons. The tips of the radial and ulnar styloid processes are resected.

Forearm Amputations

Forearm amputation should take into account the adequacy of soft tissue coverage/closure; thus, the level of transection should be aimed in between the middle and distal third of the forearm as clinically appropriate.[25,26] Anterior and posterior skin flaps are created in equal lengths. Radial and ulnar arteries are suture ligated with permanent sutures and the median, ulnar, and radial nerves are sharply divided on tension and allowed to retract. The radius and ulna are transected and smoothed about 2 cm proximal to the skin flap edges. The deep fascia is approximated with absorbable sutures and the skin is then closed (Fig. 104.7).

Elbow Disarticulation

Elbow disarticulation with preservation of the distal humerus is better for prosthesis fit onto the condyles. Anterior and posterior skin flaps are created. The brachial artery and veins are suture ligated with permanent suture, and the median, ulnar, and radial arteries are sharply divided on tension allowing them to retract. The joint capsule is removed, and either a brachialis or triceps muscle flap is used to cover the humerus. The deep fascia and skin are then approximated.

Above-Elbow Amputation

Similar to the elbow disarticulation technique, anterior and posterior flaps are created in equal length. The brachial artery and veins are suture ligated and nerves sharply divided on tension to allow retraction. Prostheses with an elbow lock mechanism are

4 cm long, so the upper arm amputation should be made 4 cm proximal to the elbow (Fig. 104.8).

Shoulder Disarticulation

Shoulder disarticulation is a complex procedure with difficult prosthesis fitting and resultant minimal function. The humeral head may be retained for aid in creating contours for a prosthesis. The deltoid and pectoral muscles with their overlying skin can offer flap coverage. The latissimus dorsi, pectoralis major, and the rotator cuff tendons are attached to the glenoid capsule. Key aspects include suture ligation of the vascular bundle, sharp division of the nerves on tension, and tensionless soft tissue coverage of the amputation site.

COMMON COMPLICATIONS

Limb amputation has a major impact on a patient’s physiology, psyche, and quality of life. Regardless of the level of amputation, the procedure is complex with multiple failure points, which can drastically alter outcomes.

Acute Phase Complications

The previously mentioned technical aspects of amputation highlight the importance of a broad and thorough knowledge of the anatomy in question. Acute bleeding and its sequalae can have a detrimental effect on the recovery of a postoperative patient. Depending on the level of amputation, the intraoperative blood loss for nontraumatic amputations can approach 500 mL.[27] Given the often older age and higher comorbid index of many of the patients undergoing amputation, even small amounts of surgical anemia can impact postoperative recovery. There are many strategies that have been applied to abrogate blood loss including individual identification and ligation of major/named vessels rather than bulk ligation, application of hemostatic agents, and the use of intraoperative tourniquets. In a 2023 Cochrane review, only one randomized controlled trial was found to evaluate the use of tourniquets, which did appear to reduce blood loss and transfusion requirements; however, the physiologic sequelae of the concomitant ischemia that comes with tourniquet use is unclear.[28] Additionally, monitoring the wound stump for evidence of hematoma is paramount because it can lead to wound breakdown, poor healing, and the need for reoperation.

Wound healing and acute ischemia are further areas where patients can suffer complications, including failure of the remnant limb to heal. Particular attention should be given to patients presenting with critical limb ischemia as the underlaying poor perfusion can predispose patients to additional, sequential amputations. Depending on the presentation, some studies indicate that nearly 18% to 20% of patients may require additional amputations and that one-third of those occur in the immediate postoperative period (30 days).[29] A careful, nuanced perioperative evaluation of limb perfusion could allow for more appropriate amputation-level selection as well as the application of preoperative and postoperative revascularization strategies.[30]

Another cause of poor stump healing is related to ongoing infection in the operative bed. This can represent either inadequate debridement when amputation is performed for infectious/diabetic complications or it could represent de novo infections. This is only compounded by tissue ischemia if present. In the first scenario, consideration can be given to staged amputations (i.e., acute guillotine followed by definitive closure) to allow interval assessment of infectious burden. Finally, regardless of the indication for amputation, consideration should be given to the use of preincision antibiotics to reduce the occurrence of surgical site infections.[31]

Chronic Phase Complications

Following the acute phase of healing, chronic complications can continue to cause patients to have a poor quality of life if not managed appropriately.

Chronic pain including phantom limb pain (PLP) after amputation is a major source of morbidity in the postoperative, posthospitalization setting. Long-standing pain in the stump (i.e., residual limb pain [RLP]) after amputation is likely a distinct entity from true PLP pain, although there maybe overlapping etiologies, symptomology, and contributing factors. Some reports indicate that up to 70% of patients will experience some form of RLP, whereas PLP can reach similar or even higher incidence.[32,33] RLP must be systematically addressed including consideration of continued ischemia, neuroma formation, and pressure points from osseous spurs or pathologic bone remodeling. PLP can be considered either based on specific complaints (pain in a portion of the limb that is no longer present) or after RLP has been ruled out. The approach to PLP management is multifaceted with no reproducible cure and can include multimodal pain-oriented pharmacologic therapy, psychoactive therapy, and sensory therapy (i.e., mirror-box therapy or augmented reality).

Pathologic healing in the form of wound contracture can also significantly impact patient outcomes. Appropriate placement of rigid immobilizers as well as aggressive early physical therapy may help prevent contractures that can impact long-term joint mobility, limb function, and prosthetic fit. Acute and chronic complications specific to amputation require high-quality preoperative and postoperative care to optimize patient outcome.

REHABILITATION AND FUNCTIONALITY

Evaluation of the patient's functional status preoperatively can significantly impact the type and level of amputation offered. Younger patients with good rehabilitation potential will recover well with a below-knee amputation. Nonambulatory patients with a leg contracture at the knee (greater than 20 degrees) would need to have an above-knee amputation to avoid further pressure-induced wounds on a below-knee amputation stump. About 65% of patients with below-knee amputation achieved ambulation with or without assistance, and only about 41% of patients with above-knee amputations ever achieve ambulation.[24] The additional energy required to ambulate with a prosthetic in below-knee amputee patients is about 10% to 40%, whereas above-knee amputees require 63% more energy expenditure.[34]

Along with an effective physical therapy program, optimal functional outcome after an amputation depends on physical and psychological health with support from a multidisciplinary team.

FUTURE DIRECTION

The Ewing Amputation

A novel modification of the transtibial amputation has been shown to prevent neuropathic pain and improve function. By creating agonist-antagonist myoneural interfaces (AMIs) at the time of the amputation, the peripheral and central neural feedback processes are activated and even can emulate joints.[25] The team at Brigham & Women's Faulkner Hospital has constructed and standardized the Ewing amputation by creating AMIs that emulate the tibiotalar joint function and the subtalar joint function. With positive outcome in patients regarding their improved function status, it will be exciting to see how this novel approach will continue to evolve.

Mycotic Aneurysms

Please access Elsevier eBooks+ to view the video for this chapter.

INTRODUCTION

The word *aneurysm* is derived from the Greek ἀνεύρυσμα, *aneurysma,* meaning “dilation.” Today, the term *aneurysm* refers to a dilation of any blood vessel to a size of 1.5 times the expected size of a normal adjacent segment of an artery. Aneurysms can be classified based on their morphology, size, anatomic location, and etiology, which are described later. The effective description of an aneurysm is important because it influences surgical indications and the surgical approach.

Peripheral and visceral aneurysms, although less common than aortic aneurysms, can represent a significant cause of morbidity and, rarely, fatality in patients. The most common cause of peripheral and visceral aneurysms is atherosclerotic degeneration; however, several etiologies exist and must be understood by the treating physician. Degenerative aneurysms are frequently fusiform in morphology and often associated with other degenerative aneurysms elsewhere in the body, most commonly the aorta. Peripheral aneurysms are often asymptomatic; however, when they present symptomatically, it is usually with symptoms of end-organ complications secondary to thromboembolic events. Rarely, the free rupture of an intraperitoneal or intrathoracic aneurysm may lead to death by hemorrhagic shock. The exclusion of the aneurysmal sac and restoration of arterial perfusion are the primary goals of any intervention because of these risks. Most of this chapter will focus on true aneurysms of the viscera and upper and lower extremities. With the increasing prevalence of endovascular therapies by multiple specialties, posttraumatic pseudoaneurysms are increasing in prevalence, and, as such, a discussion of iatrogenic false aneurysms is included. Discussion of mycotic aneurysms is outside the scope of this chapter.

Size and Morphology

The first step in describing irregularity in an arterial wall is to assess the size and morphology of the blood vessel. A true aneurysm is a dilation of all three arterial wall layers (intimate, media, adventitia) to a size greater than 1.5 times the diameter of healthy arterial tissue just proximal or distal to the region in question. An abnormal dilation in the blood vessel that does not meet this criterion is described as *ectatic.* A false aneurysm, often described as a pseudoaneurysm, is a focal disruption of all three layers of the native arterial wall. Pseudoaneurysms are typically the results of an iatrogenic injury or trauma. The extravascular blood generated by such an injury is contained by a wall of connective tissue or hematoma and is at high risk of rupturing.

The shape of a true aneurysm can be described as fusiform or saccular. Fusiform aneurysms are asymmetric increases in the entire diameter of the affected blood vessel, whereas saccular aneurysms are described as localized, asymmetric, or eccentric outpouchings arising from a focal weakness in the arterial wall. Most peripheral aneurysms are fusiform. This is because the most common cause of peripheral aneurysms is atherosclerotic degeneration of the concentric arterial wall. The risk of rupture and thromboembolic events has been relatively well characterized for most peripheral arterial fusiform aneurysms. These risks are generally less well understood for aneurysms with a saccular morphology. However, it is believed there is an increased risk of rupture, and, as such, saccular aneurysms require repair at smaller diameters. However, the surgical management of a saccular aneurysm is still dependent on symptoms, size, growth rate, and ability to perform such a repair, just as for fusiform aneurysms.

It is important to distinguish the difference between an arterial aneurysm and arteriomegaly. Classically arteriomegaly has been described as large, smoothly dilated, and commonly tortuous arteries without focal segments of dilation. This is contrasted to aneurysmal arterial tissue in which there is a focal dilation of a blood vessel, often with an irregular intima, secondary to atherosclerotic plaque. Often, aneurysms develop intraluminal thrombus that can help distinguish an aneurysm from arteriomegaly. Arteriomegaly appears to have a strong familial association, with approximately 36% of patients having a family history of arteriomegaly or aneurysms in a first-degree relative. Furthermore, patients with arteriomegaly are at increased risk of aneurysm formation.[1]

Etiology

Degenerative

Degenerative and *atherosclerotic* are terms used interchangeably to describe the most common ideology of peripheral aneurysms. Although aneurysm formation appears to be associated with atherosclerotic disease, a causal relationship between atherosclerosis and aneurysmal formation has not been established. Atherosclerotic occlusive disease and aneurysmal disease do share several common risk factors, including smoking, older age, male sex, and hyperlipidemia. However, the "degenerative" aneurysm most likely refers to a few different unidentified etiologies, and the involvement of atherosclerotic plaques in the disease process is likely multifactorial.[2] Contrary to atherosclerosis, diabetes appears to be protective from the development of degenerative aneurysmal disease. This may be partly due to the high frequency of metformin use in the diabetic population. Patients with abdominal aortic aneurysm (AAA) and type 2 diabetes who were taking metformin to manage their diabetes had slower rates of aneurysm progression when compared with diabetics not taking the drug.[3]

Recent studies have demonstrated that the immune system is critical in degenerative aneurysm formation. The presence of inflammatory cells, upregulation of adaptive and innate immunity genes, and degradation of collagen and elastin have supported this. Almost all inflammatory cell lines have been shown to infiltrate arterial walls in diseased tissue.[4] These cells organize and produce immune-related structures, such as inflammasomes and neutrophil extracellular traps, that have been associated with aneurysm tissue. In addition, cytokines and protease secreted by inflammatory cells likely contribute to the disease process. Although inflammation and extracellular matrix degeneration are hallmarks of aneurysm formation, the inciting cause is unknown. Current hypotheses include activation of the immune system by infectious agents either directly or through systemic signals[5] and autoimmune dysregulation.

Smoking remains the most significant risk factor for the development and growth of atherosclerotic aneurysms[6]; therefore, it is the top modifiable risk factor to reduce aneurysm growth and associated complications. Fortunately, there has been a significant decrease in the incidents of AAA-related mortality as the rate of smoking has decreased in the general population. It is unclear whether this applies to the incidents of peripheral arterial aneurysms and their associated complications.

Dissection Associated

Arterial dissection is described as the separation of the intima from the arterial media with subsequent extension of this separation in its anatomic plane longitudinally along the vessel. Acute occlusion, either static or dynamic, and aneurysm formation are the two main morbidities linked to arterial dissection. Because the arterial wall is dependent on the three layers to maintain structural integrity, a disruption in the arterial wall can lead to aneurysmal degeneration. The weakened artery can rupture in the acute setting. More frequently, the vessel undergoes a slow, progressive dilation over time. Spontaneous dissection most commonly occurs within the aorta; however, it can occur within peripheral and abdominal arteries as well. In the peripheral vasculature, arterial dissections are most associated with atherosclerotic disease. In younger patients without common risk factors of atherosclerosis or evidence of the disease process on imaging, segmental arterial mediolysis (SAM) should be considered as a rare cause of arterial dissection. SAM should be considered in the differential for any young patient with an aneurysm or dissection in an unusual location because this can be a life-threatening diagnosis.

Inflammatory

The inflammatory aneurysm was first described in 1972[7] as an entity distinct from degenerative aneurysms by the existence of a thick arterial wall encased with extensive fibrotic adhesions that incorporate adjoining tissues. Axial imaging often demonstrates a thick inflammatory "rind" on the exterior of the affected blood vessel. This rind can involve adjacent structures, making this class of aneurysms notoriously difficult to treat operatively.

Tissue from inflammatory aneurysms often demonstrated atherosclerotic changes within the intima. The primary difference between the degenerative and inflammatory etiology is within the adventitia. The adventitial layer is thicker and frequently infiltrated with inflammatory cells.[8] The role of plasma cells in this disease process is particularly important because approximately 40% to 50% of all inflammatory aneurysms contain IgG4-positive plasma cells.[9] Interestingly, neutrophilic infiltration and thick atherosclerotic plaques are more often seen in patients with non–IgG4-related inflammatory aneurysms. In these patients, IgG4-positive plasma cells are rare.

Some inflammatory aneurysms are associated with forms of large- and medium-vessel vasculitis. Other rare inflammatory diseases, such as Behçet disease, Cogan syndrome, and cystic medial necrosis, have components of arterial inflammation that have been associated with aneurysmal degeneration. Tissue biopsy is the gold standard for the diagnosis of vasculitis and related inflammatory diseases. When tissue samples are not obtainable, angiography can be helpful in assessing the specific type of arteritis. Asymmetric areas of segmental stenosis with aneurysm formation are characteristic of vasculitis on angiography. More common causes of aneurysms and occlusions, such as atherosclerosis and fibromuscular dysplasia (FMD), must be evaluated before making a diagnosis of vasculitis.

Finally, it is imperative to rule out an infectious etiology before any intervention. Failure to do so can lead to disastrous consequences, including implantation of surgical grafts in an infected field or administration of immunosuppressive medications during an active infection. The treatment of inflammatory aneurysms is challenging and should be managed by a multidisciplinary team, with a thorough evaluation of the differential diagnosis for aneurysmal degeneration.

Infectious

A primary arterial wall infection can lead to the formation of an arterial aneurysm. Immunocompromised patients, such as those with HIV or diabetes, those taking immunosuppressive or immunomodulatory drugs, and those undergoing chemotherapy, are at higher risk.[10] The incidence of infectious aneurysms is also increased in patients who inject drugs, specifically at blood vessels near the site of injection. In early studies, the femoral artery was the most common site of infected aneurysms, followed closely by the abdominal aorta. However, virtually any infected blood vessel can become aneurysmal, and a wide variety of pathogens can be responsible.

Traumatic and Iatrogenic

Traumatic and iatrogenic aneurysms are typically the result of direct transmural arterial injury, resulting in the formation of a pseudoaneurysm. Typically, this occurs in the setting of penetrating injury where a small segment of the artery is damaged, allowing extravasation of blood that is subsequently contained by solidifying hematoma or extravascular connective tissue. Blunt trauma and shearing or traction injuries can also lead to transmural damage and subsequent aneurysm formation. With the increasing prevalence of endovascular procedures in many specialties, the incidence of iatrogenic aneurysm formation at the arterial access site is becoming more prevalent. Iatrogenic aneurysms are the direct result of inadequate closure of the intentionally created arteriotomy.

Congenital or Developmental

Collagen and elastin are the primary structural components of the extracellular matrix within arterial walls. These components vary by type and quantity throughout the vascular tree and are critical in maintaining the strength and elasticity of the arterial wall. Therefore, any disease that affects the integrity of these structural proteins can affect the integrity of the vascular wall. Connective tissue diseases are a family of genetic conditions in which the structural integrity of collagen or elastin is affected. This can be through genetic mutations of the collagen and elastin genes themselves or through alterations in the assembly of these proteins. Patients who develop a disruption in the integrity of collagen or elastin are inherently predisposed to degeneration and loss of arterial structural integrity. This often leads to aneurysm formation, spontaneous arterial dissections, and even arterial rupture.

The most well-known connective tissue disorders affecting the vascular system include Marfan syndrome, Loeys-Dietz syndrome, familial thoracic aortic aneurysm and dissection, and vascular-type Ehlers-Danlos syndrome. Patients with these syndromes can present with multiple aneurysms in various, seemingly unrelated locations, sometimes described as *aneurysmosis*. This presentation should raise suspicion for a genetic cause.

VISCERAL ARTERY ANEURYSMS

Epidemiology

Approximately 5% of intraabdominal aneurysms affect the visceral arteries,[11] with patients most often presenting in their sixth decade of life. Historically, these aneurysms were described as *mycotic,* often syphilitic in etiology. Most contemporary visceral aneurysms are atherosclerotic or secondary to medial degeneration. Other etiologies include FMD, collagen vascular disease, inflammatory conditions (e.g., arteritis), and other rare inherited illnesses (e.g., Ehlers-Danlos syndrome and neurofibromatosis type 1).

Visceral aneurysms have an estimated incidence of 0.1% to 2%, although autopsy series suggest this may approach 10%.[12] The majority of these aneurysms are asymptomatic and diagnosed incidentally during imaging for some other diagnosis.[11] Only a minority of visceral aneurysms present with life-threatening rupture, associated with abdominal pain and hemorrhagic shock. Rupture may be intraabdominal and may result in gastrointestinal (GI) bleeding or arteriovenous fistulae in cases of sporadic erosion into structures in proximity. Although historical mortality rates approached 25% to 70%, more contemporary series suggest mortality rates as low as 10% to 15%, presumed secondary to improvements in perioperative management and the increasing use of endovascular techniques.[13] False aneurysms carry a significantly higher rate of rupture in comparison to true aneurysms. Because of their rarity and the fact that only institutional and retrospective data are available, the natural history of true aneurysms remains abstract.

Diagnosis

Occult visceral artery aneurysms are being diagnosed with increased frequency because of the increased use of advanced abdominal imaging, including magnetic resonance imaging (MRI), magnetic resonance angiography (MRA), computed tomography (CT), and CT angiography (CTA).[11] These advanced imaging modalities facilitate improved early identification and also enhance preoperative open and endovascular case planning for treatment.

Ultrasound examination of visceral vessels is limited by artifact from bowel gas and obesity, with poor sensitivity in detecting many visceral and branch aneurysms <3 cm. Axial imaging of the abdomen is recommended for this reason. Certain phenotypes that suggest FMD and connective tissue disorders should be screened for cerebrovascular and coronary artery aneurysms with additional head and neck imaging. CTA is the most commonly used modality for diagnosing and evaluating splanchnic aneurysms because it offers multiplanar, maximal-intensity projection reconstruction, volume rendering, and three-dimensional reconstructions to better assess the arterial anatomic details of the visceral and renal arteries.[11] Sections of 1-mm thickness optimize spatial resolution and enhance anatomic definition; three-dimensional reconstructions improve representation of the number and relation of all involved branches in comparison to two-dimensional catheter angiography or ultrasound. Compromised renal function increases the risk of contrast-induced nephropathy. Non- or alternate-contrast–enhanced MRA has been used to assess splanchnic aneurysms as performed with a "breath-hold" steady-state free precession sequence or time-spatial labeling inversion pulse technique. Three-dimensional rotational catheter-based angiography may benefit in planning optimal working angles for endovascular treatment and provide accurate evaluation of aneurysm necks and feeding arteries.

Treatment

Patients with visceral aneurysms generally have 10-year survival rates >80%; therefore, aneurysm treatment must offer durable long-term results with low perioperative mortality and morbidity. Although surgical repair has remained the mainstay of treatment, endovascular techniques are increasingly applied for treatment of both elective and ruptured cases. Endovascular therapy offers excellent rates of technical success, minimal morbidity and mortality, and shorter length of hospital stay. However, there is a higher risk of end-organ embolization and reintervention.[13–15] Transcatheter endovascular therapy alternatives include (1) treatment of both the aneurysm and pathologic vessel (i.e., the isolation technique); (2) aneurysm exclusion with parent vessel flow preservation (i.e., the exclusion technique); and (3) direct percutaneous puncture of the sac and subsequent embolization with thrombin, glue, or ethylene vinyl alcohol copolymer (EVOH).[16] The latter is less commonly employed for percutaneously accessible aneurysms with narrow necks. Endovascular treatments may offer decreased postoperative morbidity and mortality rates in cases of rupture compared with open surgery (2.7%–7% vs. 24%–29%, respectively).[13,17] Each splanchnic aneurysm warrants individual consideration.

Splenic Artery Aneurysm

Splenic artery aneurysms (Fig. 105.1) account for 60% of all splanchnic artery aneurysms and are the third most common intraabdominal arterial aneurysms, with a prevalence of 0.1% to 0.8% in the general population.[18] Many of these aneurysms, as proposed by Stanley et al., are attributed to arterial dysplasia, portal hypertension (HTN), local inflammation, and hormonal and hemodynamic events. As such, they are two to four times more common in females and strongly associated with multiparty.[18] HTN is a common comorbidity affecting more than half of patients with splenic aneurysm, and up to 20% will demonstrate concurrent aneurysm in an alternate arterial bed.[14] Additional etiologic risk factors include dissection and autoimmune arteritides like polyarteritis nodosa and systemic lupus erythematosus (SLE). Splenic aneurysms most often arise at branch points of the mid- and distal main splenic artery, with tortuosity of the main splenic artery being commonplace. Most splenic aneurysms are solitary and saccular, whereas 90% of patients with portal HTN will demonstrate multiple splenic aneurysms.

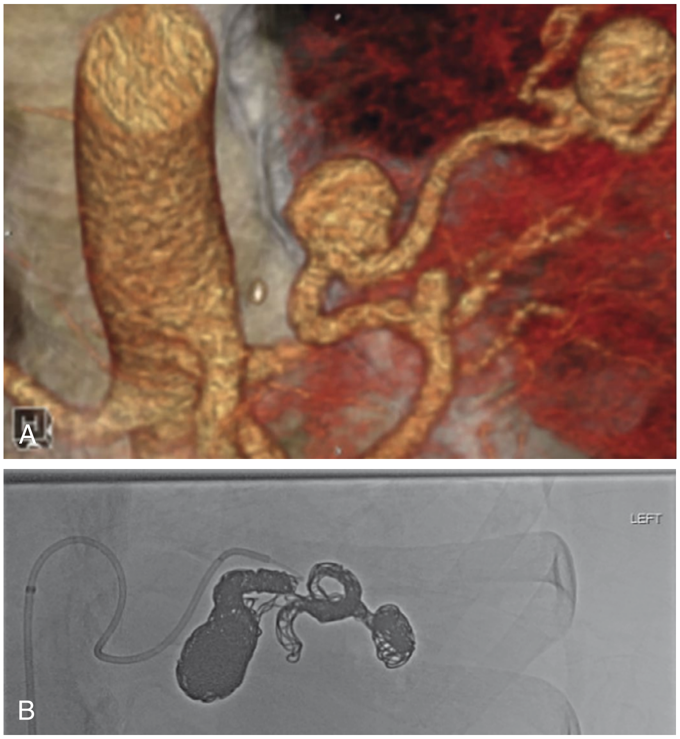

FIGURE 105.1 (A) Reformatted CT angiogram of two splenic artery aneurysms affecting the mid- and hilar artery. (B) Completion angiogram after successful coil embolization.

Splenic artery aneurysms in young females are thought to represent a more virulent phenotype. There is a tendency toward rupture that carries a devastating maternal and fetal mortality rate of >75%.[18] Pregnancy has also been associated with 20% to 50% of all ruptures, usually during the third trimester or peripartum period. Several large single-institution clinical reviews suggest aneurysms <3 cm in size can be safely observed, demonstrating slow to no growth (0.06–0.2 cm/year) with no ruptures or complications.[19] Additional risk factors for rupture include hepatic insufficiency with portal HTN, connective tissue disorder, rapid growth (>0.5 cm/year), and prior tobacco use. Splenic aneurysms typically rupture into the lesser sac with limited self-containment; subsequent hemorrhage into the peritoneal cavity results in cardiovascular collapse (i.e., the “double rupture”).

Operative Indications

- All ruptured aneurysms should be repaired emergently.
- Pseudoaneurysms of any size should be repaired.
- True aneurysms of any size should be repaired in females of childbearing age.
- Aneurysms ≥3 cm with a demonstrable increase in size or with associated symptoms in patients of acceptable risk should be repaired.
- Consider repair in patients with portal HTN, especially in patients who may require liver transplantation.
- Consider repair in patients with a nonatherosclerotic or nondegenerative splenic artery aneurysm.
- Consider repair in patients whose splenic artery aneurysm demonstrates rapid growth.

Observation with annual surveillance (CT or ultrasound) is recommended for small (<3 cm), stable asymptomatic splenic artery true aneurysms or those in patients with significant medical comorbidities or limited life expectancies.

Surgical Management

Open reconstruction. Given the abundance of collateral flow to the spleen through the short gastric arteries, the splenic artery does not routinely require preservation or revascularization.[11] Proximal and distal ligation of the aneurysm segment is a viable surgical option that has served effectively as the traditional surgical management of these aneurysms. It is still recommended when rupture is discovered at laparotomy with or without splenectomy. For distal lesions adjacent to the splenic hilum, excision with possible splenectomy may be advantageous over endovascular methods given the risk of end-organ ischemia, including splenic infarction and pancreatitis, especially when the aneurysm involves intrasplenic branches within the splenic parenchyma. Distal pancreatectomy may also be warranted on occasion in the treatment of these distal aneurysms.

Patients requiring urgent splenic artery ligation or splenectomy should be vaccinated on or after postoperative day 14 to decrease the risk of postsplenectomy sepsis resulting from organisms like *Streptococcus pneumoniae, Haemophilus influenzae type B,* and *Neisseria meningitides*. Vaccination timing should be considered 14 days before intervention for elective cases.

Endovascular therapy. Endovascular therapy has become the treatment of choice for splenic artery aneurysms. In a recent study comparing open surgery, endovascular repair, and conservative management, endovascular treatment was found to be the most cost-effective and maintain the highest quality of life.[20] The classic endovascular isolation technique is appropriate for most splenic artery aneurysms in which the risk of distal ischemia is mitigated by collateral supply. From a percutaneous femoral approach, a secure triaxial platform can be established consisting of a sheath-guiding catheter positioned across the celiac trunk into the proximal splenic artery, through which a catheter is advanced into the afferent artery and aneurysm sac, and a microcatheter is advanced beyond into the efferent vessel. Steerable sheaths and catheters can mitigate the challenges of severe tortuosity. Metallic coils are the most commonly used occlusive material and offer secondary thrombosis through thrombogenic fibers and a resulting inflammatory reaction. Coil packing starts with the efferent branches. Progressive retraction of the microcatheter facilitates exclusion of the sac and afferent artery. Coils should be oversized by 10% to 20% of the native arterial diameter to mitigate the risk of migration and incomplete arterial occlusion. This technique can be challenging for large aneurysm sac sizes or when there are multiple efferent vessels that require cannulation and embolization. Partial embolization of the sac may help reduce flow into the sac, making outflow vessels more visible and accessible for cannulation. Liquid embolic agents (e.g., "glue," N-butyl cyanoacrylate glue, and EVOH) have also been described in this setting and are useful for reaching extremely tortuous and small distal arteries that are unsuitable for coil embolization. Postembolization syndrome complicates 10% to 30% of procedural cases across series and may include left upper quadrant pain, fever, ileus, platelet dysfunction, leukocytosis, and pancreatitis after embolization with and without radiographic evidence of splenic infarction. This is far more common than splenic infarction, splenic necrosis with or without abscess, and treatment failure (5%). Staged embolization should be considered for patients with multiple aneurysms and portal HTN.

Continued surveillance with CT or ultrasound imaging is critical after endovascular treatment for all treated aneurysms, even after technical success, given the aforementioned risk of recanalization (18%–30%) and resultant secondary growth and rupture.[11,21]

Hepatic Artery Aneurysm

Hepatic artery aneurysms account for 20% of splanchnic artery aneurysms, affecting males twice as often as females.[12] The majority of hepatic aneurysms are asymptomatic extrahepatic solitary lesions that primarily affect the common and right hepatic arteries. Less than 30% are intrahepatic. Iatrogenic hepatic artery pseudoaneurysms account for half of reported hepatic artery aneurysms and are increasingly in frequency as a result of increased diagnostic and therapeutic interventions that require liver penetration. True aneurysms are primarily a result of atherosclerosis, whereas polyarteritis nodosa, cystic medial necrosis, portal HTN, FMD, and other acquired arteriopathies are less common. When present, symptoms are commonly described as right upper quadrant or epigastric abdominal pain that may radiate to the back. Large aneurysms may erode into the stomach or duodenum, resulting in GI hemorrhage, or obstruct the biliary tract, resulting in biliary colic, hematobilia, or obstructive jaundice. Although the true incidence is unknown, rupture is believed to complicate a minority of hepatic artery aneurysms (20%–30%) and results in an equal distribution of hemorrhage into the peritoneum and the biliary tract, the latter resulting in hematobilia, hematemesis, and cholangitis. Rupture-related mortality is approximately 35% to 40%. The relationship of rupture risk to aneurysm size remains unclear, although a small clinical series supports a natural history of slow to null growth. The majority of ruptures are reported at an aneurysm size >2 cm, and risk factors for such include the presence of multiple aneurysms, nonatherosclerotic aneurysms (e.g., polyarteritis nodosum, Wegener granulomatosis, SLE) and female sex.[22]

Operative Indications

- Regardless of size, all pseudoaneurysms should be repaired.
- Regardless of size, all symptomatic aneurysms should be repaired.
- Regardless of size, all aneurysms associated with vasculopathy or vasculitis should be repaired.
- True aneurysms >2.0 cm in diameter in low-risk patients should be repaired.
- If open repair is required, true aneurysms >5.0 cm among high-risk patients should be repaired.

Surgical Management

Open reconstruction. Given the possibility of central liver necrosis despite adequate collateral flow by endovascular exclusion, open surgical revascularization using autologous vein conduit is recommended when endovascular stent-graft exclusion is not possible to maintain arterial circulation to the liver. Temporary occlusion of the hepatic artery during reconstruction may guide revascularization or ligation of the hepatic artery. More distal extrahepatic aneurysm branches are often associated with biliary inflammation, making these repairs challenging. Intrahepatic aneurysms will require resection of the lobe in which the aneurysm is located, and lobe resection is recommended for large aneurysms to mitigate the risk of significant hepatic necrosis.

Endovascular therapy. Society for Vascular Surgery (SVS) guidelines support an endovascular-first approach to all hepatic artery aneurysms if anatomically feasible, provided arterial circulation can be maintained to the liver. Covered stents facilitate aneurysm exclusion and are preferably used in vessels measuring ≥4 mm in diameter, and 1 to 2 cm is required for adequate seal proximally and distally.[16] Aneurysm branches arising off the sac to be covered should be embolized to avoid retrograde reperfusion, and dual-antiplatelet therapy is often prescribed for a finite duration (6 weeks to 6 months) postprocedure. In patients with intrahepatic aneurysms (Fig. 105.2), embolization of the affected artery is recommended.[11] Complications of embolization include

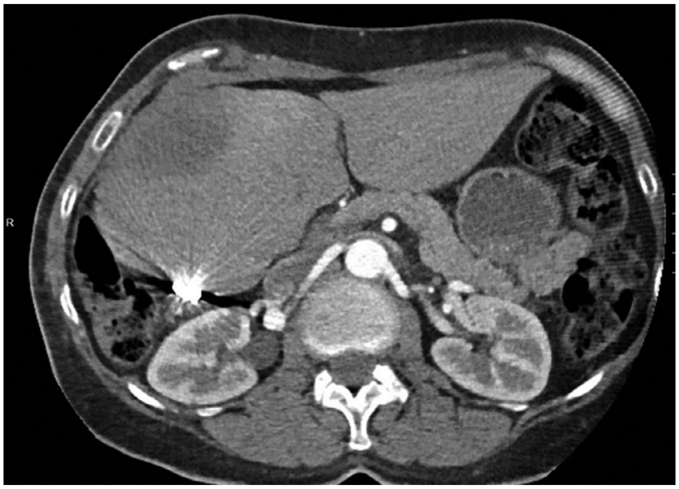

FIGURE 105.2 CT angiogram of a 52-year-old patient treated with embolization of ruptured right hepatic artery aneurysm, now with resolving subcapsular hematoma and 1.2-cm distal right renal artery aneurysm.

hepatic ischemia, abscess, cholecystitis, and possible recanalization. As described earlier, coil embolization is discouraged in patients with large parenchymal lesions or if large segments of liver are at risk of ischemia. In these patients, liver lobe resection should be considered.

Superior Mesenteric Aneurysm

Superior mesenteric artery (SMA) aneurysms account for up to 8% of all splanchnic aneurysms, and they affect males more frequently than females.[12,23,24] SMA true aneurysms (Fig. 105.3) are mainly solitary, and the etiology is less commonly attributed to atherosclerotic degeneration and more frequently associated with infection, dissection, medial degeneration, FMD, vasculitis, connective tissue disorder, and trauma. Pseudoaneurysms may occur in the setting of pancreatitis and complicated peptic ulcer disease. Concomitant HTN is common, affecting >20% of patients with SMA aneurysms, as are concurrent aortic and peripheral/splanchnic aneurysms. In contrast to other splanchnic artery aneurysms, symptoms are common. Patients may describe abdominal pain, nausea, emesis, and GI bleeding. Fever may be present in cases of mycotic aneurysm.[11] Up to one-third of patients with SMA aneurysms have a pulsatile abdominal mass on the exam. The natural history of true SMA aneurysm is that of expansion and rupture, with the additional complication risk of acute mesenteric ischemia from thromboembolism. Historically, rupture risk has been described in up to 50% of cases, and rupture-associated mortality has exceeded 50%. More contemporary series cite 30-day mortality rates as low as 12.5% to 38%, and even lower mortality after elective repair with endovascular interventions has been reported.[11,12,24] No comorbidities or aneurysm characteristics have been found to predict rupture risk.

Operative Indications

- Regardless of size, all true and false aneurysms should be repaired.
  - An exception is made for dissection-associated SMA aneurysms, for which careful observation is advised unless refractory symptoms develop.

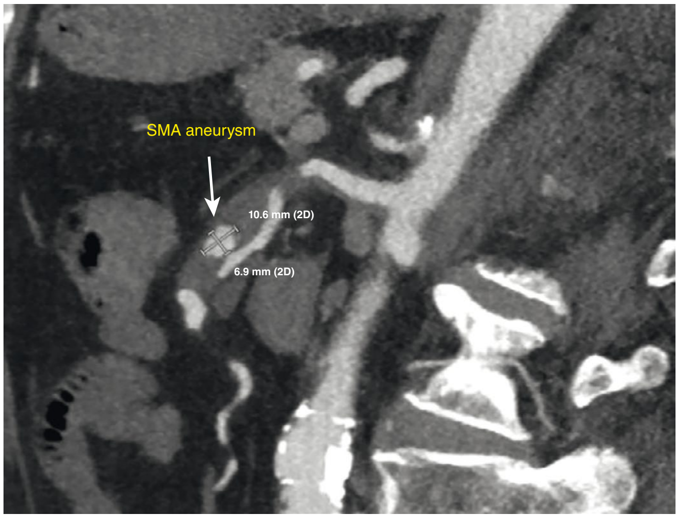

FIGURE 105.3 CT angiogram, reformatted, of a 73-year-old patient with saccular superior mesenteric artery *(SMA)* aneurysm associated with mural thrombus and associated inflammation consistent with mycotic aneurysm. *2D,* Two-dimensional.

Surgical Management

Open reconstruction. Open repair is commonly favored for SMA aneurysms, typically with an aortomesenteric bypass. Both autologous and prosthetic conduits have been described, with autologous conduit favored in cases of mycotic aneurysm and frank contamination complicating intestinal ischemia.[14] Aneurysmorrhaphy and simple ligation of efferent and afferent branches (in those patients with appropriate collateralization) have also been described with success, especially for focal, saccular aneurysms.[12,23] Open resection may require intestinal resection, particularly in symptomatic patients.

Endovascular therapy. Endovascular SMA aneurysm exclusion with stent grafting and embolization have been increasingly employed for patients with severe comorbidity. Aneurysms with a small neck distal to the SMA origin may be conducive to transcatheter embolization, provided angiographic determination of collateral flow is adequate.[24] Endovascular techniques remain limited by thromboembolic risks to intestinal circulation and endoleak.

Celiac Artery Aneurysm

Celiac artery aneurysms (Fig. 105.4) account for approximately 4% of all splanchnic aneurysms, affecting males more frequently than females.[25,26] Historically, celiac artery aneurysms were primarily associated with infection (syphilis or tuberculosis) and primarily diagnosed postmortem. Contemporary etiologic risk factors include primarily atherosclerosis, developmental risk

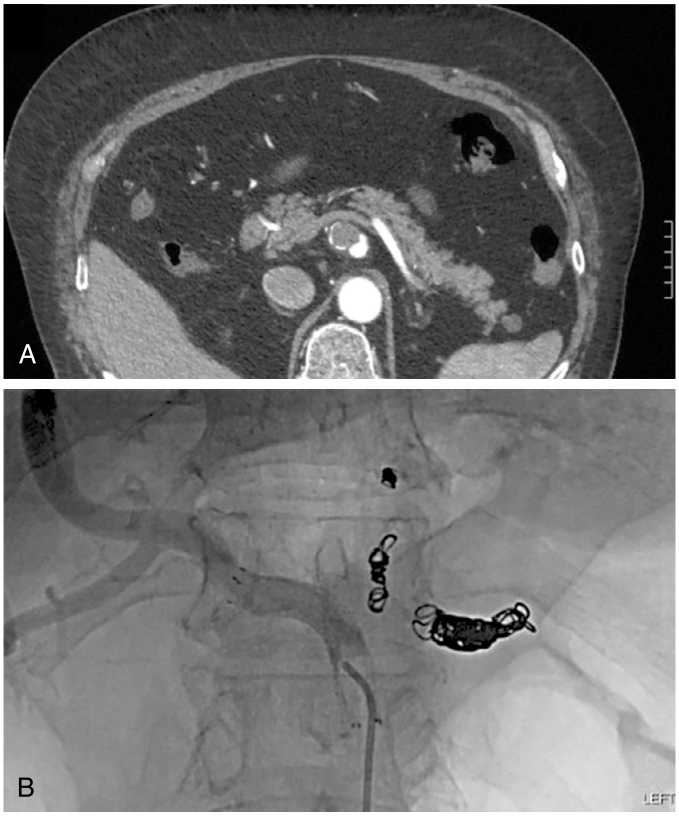

FIGURE 105.4 (A) CT angiogram of an 82-year-old patient with an enlarging >3-cm celiac aneurysm. (B) Completion angiogram after coil embolization of the left gastric and splenic arteries plus covered stenting of the celiac aneurysm extending into the common hepatic artery.

factors such as common celiacomesenteric trunk, arterial dysplasia with medial degeneration, collagen vascular disorder, trauma, and dissection. As with other visceral aneurysms, concurrent HTN is common (20%), as are aortic aneurysms (18%–40%) and alternate splanchnic aneurysms (38%). Celiac artery aneurysms are mainly asymptomatic, and clinical exam may reveal an abdominal mass or bruit. Historically, rupture complicated approximately 70% of celiac artery aneurysms, resulting in near-certain mortality, although more contemporary series support rupture rates of 13%, with associated 50% mortality. Rupture has been described in aneurysms ranging in size from 2 to 6 cm, with rates of 5% in aneurysms sized 15 to 22 mm and rates up to 75% in aneurysms >32 mm.[26] Risk factors for such have not been clearly elucidated, although aneurysmal degeneration is rare in those patients with associated dissections and poststenotic dilation (i.e., median arcuate ligament syndrome).[27]

Operative Indications

- All ruptured aneurysms should be emergently repaired.
- Regardless of size, all pseudoaneurysms should be repaired.
- True celiac artery aneurysms >2 cm with a demonstrable increase in size or associated symptoms should be repaired in patients of acceptable risk.
- Surveillance is recommended for stable asymptomatic aneurysms <2 cm or in patients with significant medical comorbidities or limited life expectancy.

Surgical Management

Open reconstruction. Aneurysmectomy with arterial reconstruction remains the preferred treatment for celiac artery aneurysms. Surgical revascularization may be accomplished by primary arterial-arterial anastomosis after aneurysm resection, direct aortic reimplantation of the celiac artery or its branches, or aortohepatic bypass. In general, the spleen and left gastric artery don't require revascularization. Prosthetic conduit may be favored over autogenous saphenous vein, which tends to kink. Elective surgical repair offers patients symptomatic relief, with up to 5% risk of perioperative mortality. The procedure of aneurysm ligation and resection without reconstruction has been endorsed, especially for rupture and patients with adequate foregut collateral circulation. This procedure carries a risk of perioperative hepatic and intestinal ischemia, necrosis, and patient mortality.[25,26]

Endovascular therapy. Endovascular options for aneurysm treatment are increasingly described.[11] The absence of a proximal landing zone may limit endovascular exclusion by covered stent grafting or embolization because these aneurysms typically affect the proximal celiac trunk.[28] Coil embolization of the left gastric and splenic arteries may be required to obtain a proximal seal (see Fig. 105.4). Transcatheter embolization may be lifesaving in cases of rupture, at the risk of perioperative hepatic and intestinal ischemia.

Gastric Artery Aneurysm

Gastric and gastroepiploic artery aneurysms account for approximately 4% to 5% of splanchnic aneurysms, affecting males more frequently than females by threefold.[12] These nonatherosclerotic aneurysms are primarily associated with arterial dysplasia, SAM, and periarterial inflammation (i.e., pancreatitis and vasculitis).[29] Gastric artery aneurysms are 10 times more common than gastroepiploic artery aneurysms. Although patients may present with abdominal pain, up to 90% of patients have historically presented acutely ruptured, with GI bleeding more common than intraperitoneal rupture.[21]

Operative Indications

- Regardless of the size, all true and false aneurysms should be repaired.

Surgical Management

Open reconstruction. Surgical management is of historical significance and was previously reliant on simple arterial ligation or excision without reconstruction. Intramural aneurysms require wedge excision of the involved gastric wall.

Endovascular therapy. Catheter-based embolization of these aneurysms has become the standard of care for first-line treatment, with multiple case reports and small series documenting successful aneurysm occlusion with coils and thrombin injection.[11,28]

Gastroduodenal and Pancreaticoduodenal Arterial Aneurysm

Gastroduodenal and pancreaticoduodenal artery aneurysms account for <2% of splanchnic aneurysms, with males having a fourfold increased risk compared with feamles.[12] Etiologic risk factors include predominantly periarterial inflammation resulting from pancreatitis, followed by arteriosclerosis, congenital medial degeneration, and trauma. Noninflammatory aneurysmal degeneration in this collateral arcade is hypothesized to be a sequelae of inordinately high-volume blood flow (Fig. 105.5) in the setting of concomitant celiac artery stenosis or occlusion.[30] Unlike other visceral aneurysms, patients frequently describe abdominal pain. Large aneurysms may cause additional symptoms of gastric outlet obstruction.[23] Rupture is common, complicating up to 75% of inflammatory and 50% of noninflammatory aneurysms, most often resulting in GI bleeding and, less commonly, bleeding into the biliary or pancreatic ductal systems, peritoneum, or retroperitoneum.[30] Rupture-associated mortality is 20% to 50%.[30] Rupture has been described at a small median size of 12 mm, with rupture reported in aneurysms <1 cm in diameter. It remains unclear if aneurysm size is a risk factor for rupture in this location.

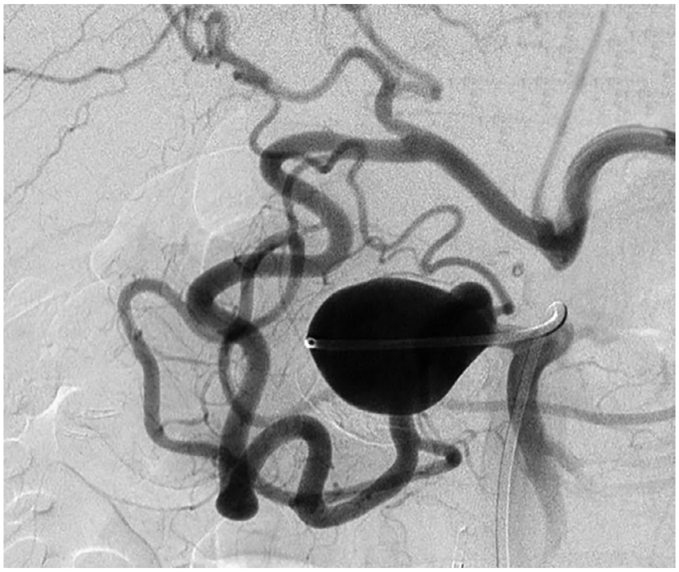

FIGURE 105.5 Angiogram demonstrating large gastroduodenal aneurysm.

Operative Indications

- Regardless of the size, all true and false aneurysms should be repaired.

Surgical Management

Open reconstruction. Open reconstruction of these aneurysms is technically feasible, with low perioperative morbidity and mortality for nonruptured aneurysms employing techniques of ligation and excision with or without end-to-end anastomosis.[31] Celiac stenosis or occlusion is commonly associated with aneurysms of the pancreaticoduodenal arcade, and a low threshold for celiac revascularization should be considered in patients with symptoms of chronic mesenteric insufficiency at baseline or when there is a risk of compromising end-organ perfusion with aneurysm treatment. In cases of median arcuate ligament syndrome, celiac revascularization can be achieved with division of the median arcuate ligament and celiac plexus with or without aortoceliac or aorto-hepatic bypass.

Endovascular therapy. Percutaneous embolization of pancreaticoduodenal and gastroduodenal artery aneurysms is recommended as first-line therapy by the SVS guidelines for intact and ruptured aneurysms.[11] A triaxial system, as described earlier, inclusive of a microcatheter provides stable support through tortuous vessels. Coil embolization is recommended as the treatment of choice, with liquid embolic agents as an alternative for appropriate anatomy. Covered stenting and stent- or balloon-assisted coil embolization are recommended for patients in whom coil embolization is not feasible.[11] For aneurysms with a wide neck but sufficient size and morphology to retain an embolic coil cast, balloon-assisted embolization can create the initial formation of a “cage” to enhance success. This technique involves the placement of a balloon catheter in the parent vessel across the aneurysm neck with a microcatheter positioned concurrently into the sac. The balloon is inflated while the coils are inserted to prevent prolapse or migration into the parent vessel lumen. For aneurysm necks whose width prohibits balloon remodeling, stent-assisted coil embolization can be considered as an alternative. This technique involves placing an uncovered stent in the parent vessel across the aneurysm neck with the microcatheter placed into the sac alongside the stent or through its mesh struts for embolization.

Flow-diverting multilayered stents are an additional treatment modality for patients with suitable anatomy. First introduced for the treatment of intracranial aneurysms, flow-diverting stents are placed in the parent artery to improve laminar flow and reduce blood intrusion within the aneurysm sac. This promotes aneurysm thrombosis. The device boasts a tight micromesh design to induce flow “diversion” through the parent vessel and sac thrombosis while preserving the patency of efferent branches and collateral side branches. These stents are more flexible than stent grafts, although their use is limited by size availability (currently up to 8 mm) and cost.

Renal Artery Aneurysm

Renal artery aneurysms (RAAs) are rare, with an incidence that approximates 1%.[32] Most aneurysms are asymptomatic. Rarely, patients may describe flank pain, abdominal pain, and hematuria. Most RAAs are saccular in nature, but they can be fusiform or intralobar. Rundback et al. have classified RAAs into three categories: type 1 = saccular aneurysms arising from the main renal artery, type 2 = fusiform aneurysms, and type 3 = intralobar aneurysms arising from small segmental arteries or accessory arteries.[33] RAAs occur more often on the right side (61%), and the most common locations in order are the renal bifurcation, followed by the renal pelvis, the distal renal artery, the midrenal artery, and, rarely, the proximal renal artery.[34] Nearly two-thirds of patients have FMD, and concurrent arterial aneurysms affect the aorta, visceral, and iliac arteries in up to 30% of patients. As such, screening cerebrovascular, mesenteric, and iliac beds is prudent, especially in young females.

The natural history of RAAs appears to be that of slow to null growth, with contemporary series estimating a median annualized growth rate of 0.06 to 0.6 mm.[34] Aneurysm growth rate does not seem to be affected by aneurysm morphology or calcification, although risk factors for rupture include pregnancy, HTN, and associated arteriovenous fistula. Although historical series described rupture rates as high as 14% to 30% with associated mortality of 80%, contemporary rupture rates are estimated at 3% to 5%, with nongestational mortality <10%.[32] Most ruptures are diagnosed at the time of presentation, and several authors now have supported no rupture during the surveillance of nonoperative RAAs.

HTN may be present in up to 70% to 75% of patients with an RAA.[35] Although the mechanism for HTN in RAA patients remains elusive, hypotheses include distal parenchymal embolization, compression or kinking of associated renal artery branches, and hemodynamic changes from turbulent blood flow within the aneurysm resulting in decreased distal renal artery perfusion pressures.[11] Most series suggest an improvement or cure in the majority of hypertensive patients undergoing RAA reconstruction, particularly if renovascular HTN is identified during the preoperative workup.

Operative Indications

- All ruptured aneurysms should be emergently repaired.
- Aneurysms >3 cm in patients of acceptable risk should be repaired.
- Regardless of size, all aneurysms in patients of childbearing potential should be repaired.
- Regardless of size, aneurysms in patients with medically refractory HTN and functionally important renal artery stenosis should be repaired.

Absent prospective or randomized trial data directly comparing operative repair to surveillance and acknowledging the more indolent natural history than previously suggested, contemporary data and SVS guidelines support a conservative threshold for repair. Individualized treatment that considers phenotype and genotype should be considered comprehensively because arteries in a branch location or associated with a known connective tissue disorder may warrant a more aggressive approach.

Surgical Management

Open reconstruction. RAA can be treated by a variety of surgical methods. Open surgical reconstruction remains the gold-standard technique for elective repair, offering low morbidity and mortality and a 5-year survival of nearly 90%.[36] Repair of RAAs (Fig. 105.6) most often includes in situ reconstruction, including resection and primary angioplastic closure, patch angioplasty or primary reanastomosis, interposition grafting, or bypass (i.e., aortorenal or spleno-/hepatorenal). The tailoring technique, which includes a partial resection of the aneurysm with direct suture of the remaining arterial wall, has been proposed as an additional open option. Ex vivo repair with or without autotransplantation of the kidney remains an alternative approach, of particular use in those patients requiring complex or distal

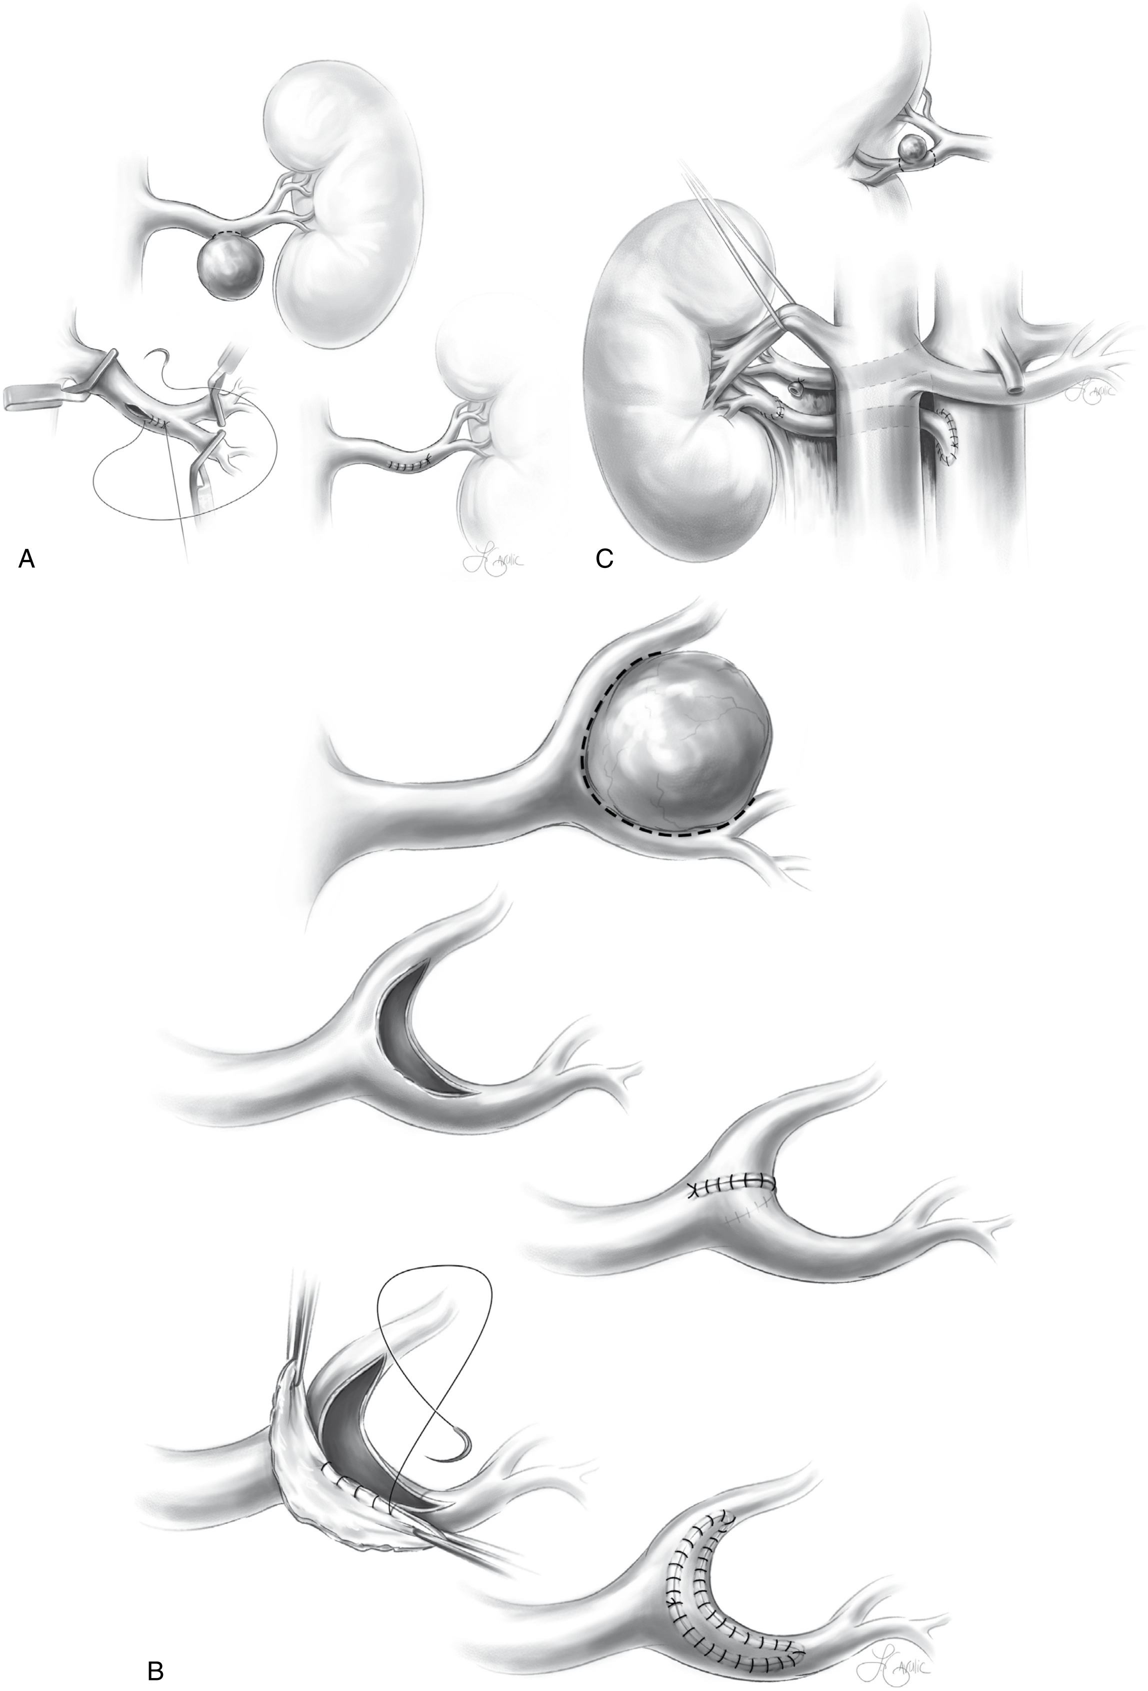

FIGURE 105.6 Renal artery aneurysms may be reconstructed by a variety of techniques not limited to resection with primary repair (A), resection with angioplastic closure of the defect in a transverse fashion or patch angioplasty (B), and resection with aortorenal bypass (C). (Adapted from Coleman DW, Stanley JC. Renal artery aneurysms. *J Vasc Surg*. 2015;62[3]:779-785.)

reconstructions. Robotic and laparoscopic techniques have been reported as well. Careful attention to anatomy and location should be considered to create individualized surgical plans because few studies are available comparing surgical techniques for repair of RAAs.

Endovascular therapy. Although endovascular therapy has gained recognition and utility in the management of RAAs, only a subset of patients will fit the anatomic criteria to undergo this therapy. Traditional endovascular therapies for RAA have used coil embolization for distal and parenchymal aneurysms and stent-graft exclusion for main renal artery lesions, but the indications for endovascular repair have broadened with advancing technology to include three-dimensional detachable coils, nonadhesive liquid embolic agents, remodeling techniques (i.e., balloon- and stent-assisted coiling), and flow diverter stents, as described earlier. Technical success with endovascular means approximates 73% to 100% across series, with highly variable rates of morbidity (13%–60%) that include radiographic evidence of end-organ malperfusion and subsequent postembolization syndrome, arterial dissections, renal insufficiency, and low rates of recanalization requiring reintervention (4%–13%).[11,16,28]

UPPER EXTREMITY ANEURYSMS

Upper extremity peripheral aneurysms, including dilations of the subclavian, axillary, brachial, and distal vessels, are very uncommon relative to lower extremity peripheral aneurysms.

Subclavian and Axillary Artery Aneurysms

The literature is limited to a few case series and case reports regarding the etiology and natural history of subclavian aneurysms. As such, the true incidence of aneurysm formation in these anatomic locations is unknown.

The distribution of etiologies for subclavian and axillary aneurysms varies in prior reports. Early case series reported the most common cause to be degenerative atherosclerotic disease, followed by traumatic pseudoaneurysms and then thoracic outlet obstruction. Another early case series reported that more than half of the subclavian artery aneurysms they treated were related to atherosclerotic disease.[37] Finally, a more recent series identified thoracic outlet obstruction as the primary etiology in over 70% of cases.[38] Some risk factors have been identified, such as connected tissue diseases, arterial thoracic outlet syndrome (Fig. 105.7), poststenotic dilation from a cervical rib, and atherosclerosis. Repetitive mechanical trauma in overhead-throwing athletes can cause repeated compression and contusion of the axillary artery by the humeral head. Repeated arterial injury places these patients at risk for thrombosis and axillary artery aneurysm formation as well.[39]

The feared complication of subclavian artery aneurysms is rupture with intrathoracic hemorrhage and subsequent hemorrhagic shock. This is less common for aneurysms outside of the thoracic cavity because the potential space to collect blood is small. As such, the main devastating complication of axillary artery aneurysms is thrombosis with embolization. Thromboemboli generated from intraluminal thrombus can become lodged in small arteries, leading to focal areas of ischemic necrosis. Patients with axillary aneurysms usually do not present with acute limb ischemia (ALI) because of the excellent arterial collateral circulation around the shoulder. However, thrombosis with distal extension can disrupt collateral flow, generating acute ischemia. Thrombosis of a subclavian aneurysm is more likely to cause ALI. Thrombosis at this level would block antegrade flow to the collateral pathways of the upper extremity. Although the true natural history of aneurysms in this anatomic location has not been reported because of the rarity of the disease, it is likely similar to peripheral aneurysmal disease in the lower extremity. If left untreated, patients are expected to experience continued aneurysmal dilation followed by thrombosis, with eventual thromboembolism or ALI and upper extremity tissue loss.

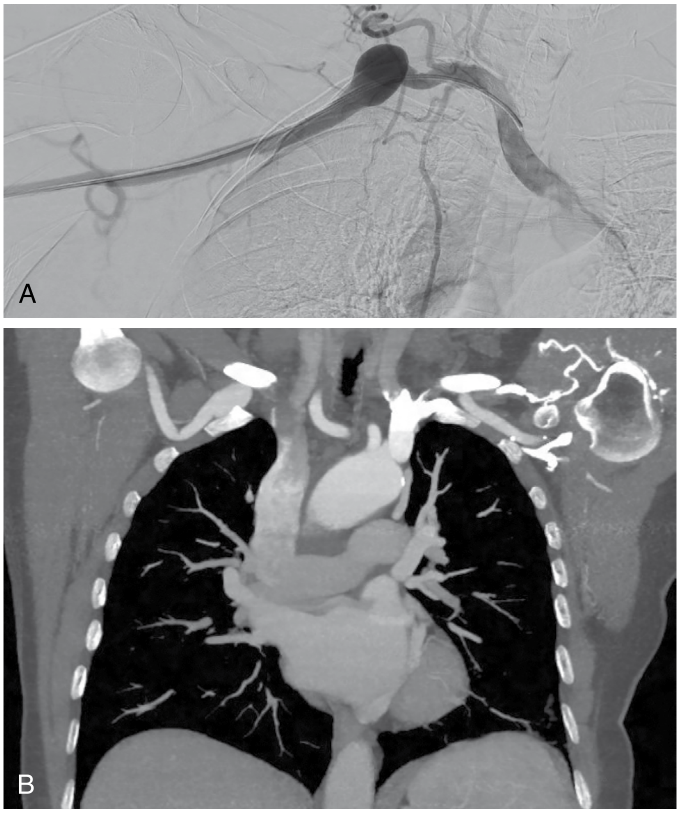

FIGURE 105.7 Axillary artery aneurysm. Catheter-directed digital subtraction angiography (A) and coronal section of reformatted CT angiogram (B) demonstrating arterial aneurysm in the thoracic outlet caused by arterial thoracic outlet syndrome.

Diagnosis

The primary presenting symptoms for patients with subclavian or axillary artery aneurysms without acute complications are shoulder pain and a pulsatile superior chest mass. Compression of the brachial plexus can cause numbness and paresthesias in the affected extremity. About a quarter present with ALI, and around 30% present with chronic limb ischemia symptoms.[38] If the patient presents without acute symptoms, duplex ultrasonography can confirm the diagnosis (Fig. 105.8). Often, CTA is appropriate to delineate baseline anatomy and aid in operative planning or to make a diagnosis if ultrasound is unavailable (Fig. 105.9).

Diagnosis of an axillary or subclavian artery aneurysm should be considered in any patient presenting with upper extremity ALI or chronic tissue loss. This is especially true if the patient has a personal or family history of connective tissue disorder, the patient is a throwing athlete, or there is suspicion for thoracic outlet syndrome.

ALI is an operative emergency. ALI in the upper extremity is relatively rare and most commonly results from a cardioembolic event. If the suspicion for a cardioembolic event is high, the

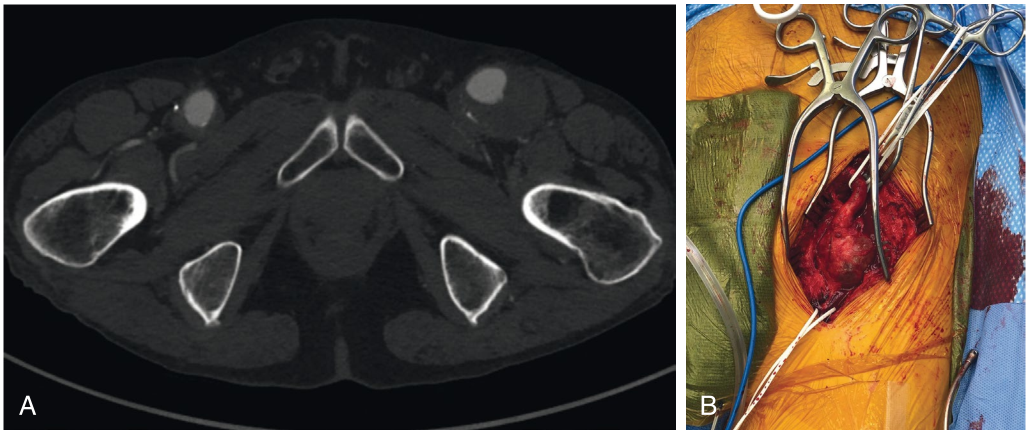

FIGURE 105.8 Intraoperative images from a brachial aneurysm reconstruction. (A) Proximal control is established at a segment of healthy artery. (B) Great saphenous vein (GSV) was obtained, the proximal anastomosis was completed, and the graft was tunneled. The aneurysm sac was incised, and branch vessels were ligated internally for hemostasis. Given the size of this aneurysm, the sac was excised, and branch vessels were ligated. The distal anastomosis was then completed. (C) Complete arterial reconstruction with reversed GSV bypass graft intact.

patient should be emergently taken to the operating room for embolectomy and revascularization. However, axillary and subclavian artery aneurysms are a rare cause of upper extremity ALI. Therefore, if the suspicion for a cardioembolic event is moderate to low, emergent CTA should be performed to obtain further anatomic data. Occasionally, a thrombosed aneurysm may be identified, which would require emergent revascularization.

Outside of the mildly symptomatic ambulatory patient and the acute patient, axillary and subclavian artery aneurysms are typically incidentally discovered on axial imaging as MRI and CT imaging modalities increase in use (see Fig. 105.9).

Operative Indications

Elective setting.

- Aneurysm related to arterial thoracic outlet syndrome should be repaired.
- Connective tissue–related aneurysms should be referred to a vascular specialist for further management of this complex disease process.
- Consider repair if intraluminal thrombus is present.

Acute setting.

- Any thrombosed aneurysm causing ALI requires emergent revascularization.
- Any ruptured subclavian aneurysm requires emergent exclusion and potential revascularization.

Surgical Management

Open reconstruction. Axillary artery aneurysms are easily treated surgically by resecting the aneurysm and grafting an interposition vein. The patient should be positioned supine with the ipsilateral arm out at a 90-degree position and shoulders slightly elevated. Commonly, an axillary roll is placed. The surgical approach is often through an infraclavicular incision that is 2 to 3 cm below and parallel to the lateral portion of the clavicle (Table 105.1). This incision can be extended distally into the deltopectoral groove to create a deltopectoral incision. Care should be given to avoid the cephalic vein. Dissection is carried down through the pectoralis fascia and between the fibers of pectoralis major. The clavipectoral fascia is incised, and pectoralis minor can be divided, providing excellent exposure of the entirety of the axillary vessels. The artery in this location runs deep to the axillary vein; therefore, the vein should be mobilized inferiorly. The cords and divisions of the brachial plexus surround the axillary artery. After proximal and distal control are established, the patient should be systemically heparinized. Vascular clamps can then be applied, and the aneurysm sac is opened.

The conduit of choice if interposition grafting is required is reversed greater saphenous vein (rGSV). If this is not available or not of adequate size and length, a prosthetic repair of the axillary artery may be carried out, preferably with externally supported polytetrafluoroethylene (PTFE). These grafts now come as heparin-bonded PTFE and provide acceptable patency.

Subclavian artery aneurysms are more difficult to treat surgically because of the exposure required for proximal control. For a distal subclavian aneurysm, a rare entity, exposure can be obtained through either a supraclavicular or infraclavicular approach (see Table 105.1). The medial clavicle can be resected to provide more proximal exposure. To do this, the supraclavicular incision is extended medially, and dissection is carried through the fascia and periosteum of the clavicle. The insertions of the sternocleidomastoid and pectoralis muscle are detached and reflected superiorly and inferiorly, respectively. Dissection around the clavicle is carefully performed, and the subclavian vein is protected while the clavicle is transected, medially dislocated, and removed. However, subclavian aneurysms are commonly proximal or even extensions of aortic arch or innominate artery aneurysms, requiring a median sternotomy for proximal control if open repair is warranted. Continuation of this incision into the supraclavicular fossa can be necessary to gain adequate exposure to the entire subclavian artery. The proximal left subclavian artery is notoriously difficult to access surgically. A left anterior thoracotomy combined with a median sternotomy and supraclavicular exposure, known as a *trap-door thoracotomy,* may be necessary (see Table 105.1).

Endovascular therapy. Generally, endovascular reconstruction that spans a mobile artery, such as the axillary artery, is discouraged. Stent fractures have been described, likely related to repetitive motion of arteries that span joints. Specifically, elevation of the upper extremity brings the axillary artery into contact with the humeral head. This can cause stent compression. If an endovascular repair of an axillary aneurysm is necessary, recommended

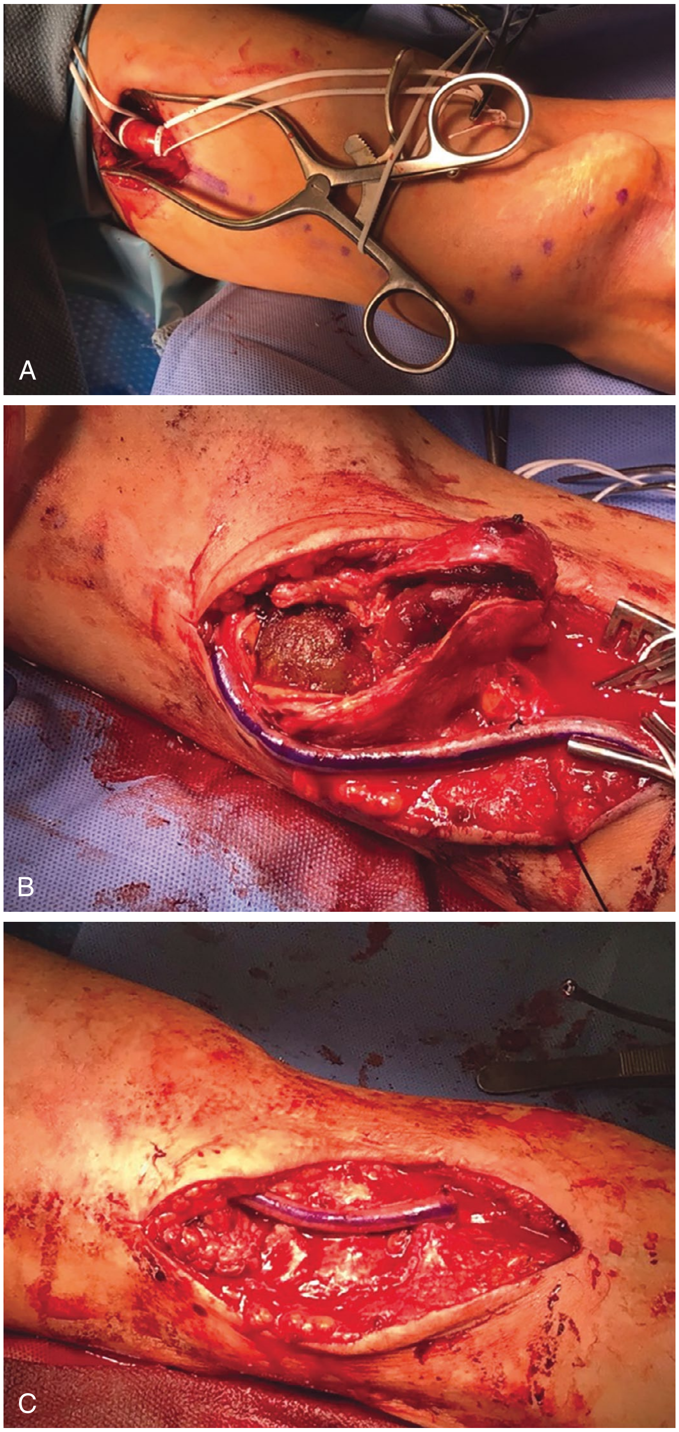

FIGURE 105.9 Common femoral artery aneurysm seen (A) on reformatted CT angiogram and (B) intraoperatively after completion of arterial dissection. Notably, the patient had bilateral common femoral artery aneurysms. The large size and extensive thrombus necessitated repair of the left common femoral aneurysm first.

only in an emergent, hemodynamically unstable patient, a self-expanding covered stent should be used over a balloon expandable stent because of its flexibility and memory retention properties.

Endovascular reconstruction of a subclavian artery aneurysm is extraordinarily complex because of the numerous bifurcations and tortuous vessels in this location. Often, retrograde common femoral artery (CFA) access is obtained, and the subclavian artery is selected through the arch or innominate artery. Caution must be taken to heparinize all patients before cannulating the aortic arch to reduce the high risk of embolic stroke when working in this area. If a wire can pass through the aneurysm into healthy tissue, a working sheath can be positioned, and a stent graft can be deployed. Alternatively, upper extremity access through the brachial artery can be obtained to eliminate the stroke risk of aortic arch cannulation. The acute rupture of a subclavian artery aneurysm can be a life-threatening event. Emergent exclusion of the aneurysm is required, and in this acute setting, an endovascular solution may be the most prudent, but it can be extremely challenging depending on anatomy and comes with a risk of stroke.

ARM, FOREARM, AND HAND ANEURYSMS

Upper extremity peripheral aneurysms are exceedingly rare and account for less than 1% of all peripheral aneurysms. Less than 0.5% involve the brachial artery (see Fig. 105.9). Brachial artery aneurysms are classically false aneurysms secondary to trauma, iatrogenic injury (dialysis access complications), drug abuse, or mycotic lesions. Occasionally they are idiopathic, but the increased prevalence of invasive interventions requiring upper extremity arterial access contributes to a large proportion of pseudoaneurysms at this location.[40] Repetitive blunt trauma, such as arterial compression from inappropriate crutch use, can cause arterial medial contusion from repetitive compression. True aneurysms can be related to type 1 neurofibromatosis, Behçet disease, and other types of vasculitis.

Causes of ulnar artery aneurysms include trauma, vasculitis, connective tissue disease, and iatrogenic injury.[41] The most common cause of ulnar artery aneurysms appears to be repetitive trauma. This is commonly seen in some athletes and patients of occupations in which repetitive trauma to the medial palmar surface is sustained, named *hypothenar hammer syndrome.* Most proximal ulnar artery aneurysms have been reported in children. There are currently only 25 reports of radial artery aneurysms in the literature,[42] and these are most often pseudoaneurysms caused by trauma or a complication of vascular access.

Brachial, ulnar, and radial artery aneurysms can cause distal ischemia and tissue loss of the hand. Exsanguination from rupture is rare in this location, but compressive symptoms are common because peripheral arteries are often near nerves. Uncontained ruptures of pseudoaneurysms can cause ischemic changes to the overlying skin and eventual skin necrosis.

Diagnosis

Diagnosis of an upper extremity aneurysm is often suggested on physical examination. A pulsatile mass with a thrill will often be observed in patients presenting with mild symptoms, such as nerve compression or pain. If the patient presents with digital ischemia or focal gangrenous changes, a firm mass in an arterial anatomic location may be observed. This is the result of thrombosis of the aneurysm and distal embolization. Duplex ultrasound is usually sufficient to confirm the diagnosis in the upper extremity, but angiography (either CT or catheter based) is often necessary to define the extent of disease, assess for arterial occlusion, and look for anatomic variants that will aid in operative planning.

Operative Indications

- All pseudoaneurysms should be repaired.
- All aneurysms with neurologic complications should be repaired.

TABLE 105.1 Operative Approaches and Considerations for Upper Extremity Arterial Exposures

ARTERY	APPROACH	SEGMENTS EXPOSED	CONSIDERATIONS
Right subclavian	Median sternotomy	Great central exposure, can be extended supraclavicularly to provide distal exposure	Can extend incision to the supraclavicular space for more extensive exposure
	Supraclavicular	Limited distal exposure	Protect the phrenic nerve
Left subclavian	Anterolateral thoracotomy	Proximal exposure and control	
	Trap-door thoracotomy	More extensive exposure	Highly morbid, trauma only
	Supraclavicular	Mid- and distal segment	Protect the phrenic nerve and identify thoracic duct
Axillary	Infraclavicular	1st and 2nd segments	Can be extended distally to deltopectoral
	Lateral	2nd and 3rd segments	Positioning may limit more distal exposures
	Deltopectoral	Entire axillary segment	Often need to divide pectoralis minor
Brachial	Medial	Excellent exposure of all but the most distal segment	Identify and protect median nerve, can ligate the deep brachial vein if needed
	Transverse or S-shaped antecubital	Distal brachial and brachial bifurcation	S-shaped incision needed if crossing antecubital fossa
Radial	Lateral volar	Distal radial	Variable radial nerve
Ulnar	Medial volar	Distal ulnar	Ulnar nerve close in proximal forearm

- Any aneurysm associated with skin changes should be repaired.
- Consider repair of true aneurysm with intraluminal thrombus or >2.5 times the native artery diameter.

Surgical Management

Open Reconstruction

Exposure of the brachial, ulnar, and radial arteries is relatively straightforward and can be achieved under local, regional, or general anesthesia (see Table 105.1). It is much safer than more proximal exposure. If hemorrhage is encountered during dissection, proximal control can be obtained with a tourniquet or direct pressure proximal to the dissection because of the superficial course of these vessels.

For wide exposure of the brachial artery, a longitudinal incision is made along the medial aspect of the upper arm just posterior to the short head of the bicep brachii (see Table 105.1). The neurovascular bundle is located just posterior to the bicep muscle, with the artery typically positioned deep to paired brachial veins and the median nerve. Care must be given to protect the median nerve. Superficial nerves at this level can occasionally be large; however, are all sensory. Additionally, if required for more proximal exposure, the deep brachial vein can be sacrificed.

The most operatively exposed upper extremity artery is the distal brachial artery at the antecubital fossa. When crossing the antecubital fossa, a transverse or “lazy-S” incision is recommended to reduce the risk of stricture (see Table 105.1). If the antecubital fossa is not being crossed, a longitudinal incision can provide better exposure of the proximal radial and ulnar arteries. The brachial artery at this location lies deep to the bicipital aponeurosis. Division of that aponeurosis provides an easy exposure.

If considering open surgical repair of a brachial artery aneurysm, direct inline reconstruction should be attempted. Typically, pseudoaneurysms can be repaired primarily without an interposition bypass graft. True aneurysms involve larger segments of the native artery, and their reconstruction will likely involve one of two strategies, interposition grafting or bypass (see Fig. 105.9). If the entirety of the true aneurysm is surgically accessible, the aneurysm can be completely ligated and excluded. Anatomic reconstruction with an interposition graft sewn end to end can be performed. The aneurysm can be ligated and excluded. If compressive symptoms are present, the aneurysm can be decompressed with this approach. If the aneurysm is long or involves a surgically inaccessible location, a bypass graft that is tunneled subcutaneously is often the best approach (see Fig. 105.9). For either approach, long-term outcomes and patency are thought to be excellent.

For ulnar artery aneurysms, the type of repair typically depends on the patient’s distal perfusion. If ischemic symptoms are present, then ulnar artery reconstruction is required. If there are no signs of ischemia, then ligation of the aneurysm can be considered. Rarely is a bypass required to be performed.[41] There is no clear consensus about whether to ligate or reconstruct the radial artery. Some have proposed revascularization whenever possible, whereas others have argued for selective revascularization depending on the collateral circulation to the hand.[42] The latter suggests revascularization only if an incomplete palmar arch is present, in which ligation of the radial artery would lead to digital ischemia. The reconstruction of the distal upper extremity arteries should be done in an end-to-end fashion, making sure there is no tension on completion. If this is required, the conduit of choice is autologous vein.

Endovascular Therapy

The peripheral arteries of the upper extremity are easily surgically assessable. Surgeries can be performed in this location under local and regional anesthesia. This fact, in conjunction with the small caliber of the distal upper extremity arteries, has led to little role for endovascular reconstruction in this anatomic location.

LOWER EXTREMITY ANEURYSMS

Femoral Artery Aneurysms

Femoral artery aneurysms (see Fig. 105.8) represent approximately 3% of all peripheral aneurysms, making them the second most common site after popliteal artery aneurysms (PAAs), with an incidence of approximately 5 per 100,000 people.[43] Aneurysms in this location are most commonly in the CFA (~57%) and less commonly found in the profunda femoris (~17%) and superficial femoral arteries (~26%). About one-quarter are incidentally discovered, and there is a male predominance. It is estimated that 50% to 90% of patients will have a concomitant AAA, an even stronger association than with PAAs.[43] In addition, up to one-third of patients will have a contralateral femoral aneurysm.

Most femoral aneurysms are related to degenerative atherosclerotic disease. This agrees with the most common primary risk factors being smoking and HTN. Cases of femoral artery aneurysms in patients with Behçet disease, Parkes-Weber syndrome, Marfan syndrome, and Wegener granulomatosis have been reported.[43] The natural history is unclear because of the rarity of the disease. Yet it appears rupture is uncommon, occurring in about 4% to 15% of cases. The primary concerns are thrombosis, embolism, and limb ischemia, as is the case with most aneurysms of the extremities. Unfortunately, the most common presentation in up to 65% of cases is lower extremity ischemia. This manifests as either claudication or critical limb ischemia from embolization.

Diagnosis

Diagnostic workup starts with a focused history and physical examination. Approximately 30% to 40% of patients will be asymptomatic, likely presenting with an incidentally found aneurysm. For symptomatic patients, about 30% to 40% will present with local symptoms of pain and tenderness or compressive symptoms of neuropathic pain and lower extremity edema. A history should elicit risk factors such as smoking, hyperlipidemia, and IV drug use. A full vascular exam with specific attention to ipsilateral distal pulses and pulsatile abdominal or popliteal fossa masses should be performed. Physical examination may reveal a pulsatile mass at the site of concern.

Noninvasive testing with duplex ultrasonography is cost-effective and has a high sensitivity and specificity. Subsequent axial angiography, such as CT or MRI, and geography are invaluable to further define the anatomy, look for intraluminal thrombus, and aid in case planning. All patients should be screened for both abdominal aortic and contralateral femoral aneurysms.

Operative Indications

- All aneurysms >3.5 cm in diameter should be repaired.
- All symptomatic aneurysms (claudication, nerve compression, rupture, and ischemic symptoms) should be repaired.
- Consider earlier repair in aneurysms with intraluminal thrombus.
- Consider earlier repair in aneurysms with a saccular morphology.
- Consider repair in expanding femoral aneurysms.

The primary goal of surgical reconstruction is the prevention of thrombosis and embolization, worsening compressive symptoms, and rupture.

Surgical Management

Open reconstruction. The goal of an open surgical operation is the exclusion of the aneurysm with arterial reconstruction. The CFA is the extension of the external iliac artery as it passes deep to the inguinal ligament. It lies medial to the femoral nerve but lateral to the common femoral vein within the femoral sheath. The femoral sheath is formed by the continuation of the transversalis fascia anteriorly and the continuation of the iliopsoas fascia posteriorly. Exposure of the femoral arteries is easiest through the femoral triangle. The triangle is bordered by the inguinal ligament superiorly, the medial border of the sartorius muscle laterally, and the medial border of the abductus longus medially.

Exposure is primarily obtained through a longitudinal incision directly over the femoral artery. Arterial identification should not be difficult in patients with aneurysmal disease; however, if needed, preoperative ultrasound can assist in planning the surgical incision. Approximately one-third of the incision should extend proximal to the inguinal ligament. It is crucial to identify the location of the inguinal ligament using bony landmarks in patients with a large pannus or morbid obesity. This structure is often more proximal than thought if only using the inguinal creases as a landmark. Dissection is carried down through the subcutaneous fat, medial to the sartorius muscle. Any encountered lymphatics or lymph nodes should be ligated. The fascia lata of the thigh will be opened medial to the medial border of the sartorius muscle, followed by the femoral sheath. These structures are often divided simultaneously, providing arterial access.

The proximal dissection of the femoral artery is carried out at least to the border of the inguinal ligament. The aneurysm often extends beneath the inguinal ligament, and further exposure is needed to provide proximal control. The inguinal ligament can be mobilized and retracted superiorly to increase retroperitoneal visibility. If additional proximal exposure is needed, the ligament can be divided. This must be repaired at the case conclusion to avoid a femoral hernia. Distally, the dissection will extend until the superficial femoral artery and profunda femoris artery are visualized and encircled with vessel loops.

After obtaining control, the aneurysm sac is opened. Larger or more inflamed pathologies can be left in vivo. This can prevent injury to surrounding structures. Reconstruction of a true femoral artery aneurysm typically consists of interposition grafting. In this anatomic location, prosthetic grafts are often preferred to autologous venous conduits because of size discrepancy. Prosthetic grafts can better match the native arterial size and have similar patency rates to autologous interposition grafts. Any concern for infection should change this consideration. If the aneurysm is isolated to the CFA, reconstruction can be performed with a short interposition graft. Any aneurysm that extends to the femoral bifurcation will require more complex strategies (Fig. 105.10). In this setting, an interposition graft is created from the CFA to either the superficial femoral or profound femoris. A jump graft is then sewn from the other femoral branch onto the newly placed interposition graft. A femoral artery branch can be directly anastomosed to the interposition graft if there is enough redundancy.

Endovascular therapy. As seen with axillary artery aneurysms, endovascular repair is typically avoided because the femoral artery crosses a joint and is highly mobile. This can lead to stent fracture. Additionally, it is the rare CFA aneurysm that presents with enough distal seal length needed for successful covered stent placement. Endovascular treatment of the femoral arteries should be reserved for the emergent setting. In this setting, a covered self-expanding stent should be used.

Popliteal Artery Aneurysms

History

PAAs have been described since antiquity, most of which were traumatic false aneurysms. The anatomist and surgeon John Hunter described a personal series regarding the operative approach to popliteal false aneurysm (the “coachmen’s knee”), recognizing the need to ligate the artery in a normal-appearing segment proximal to the aneurysm.[44] Modern understanding of the anatomy, pathology, and natural history of PAAs was largely acquired in the latter half of the last century, coincident with the development of reliable bypass techniques. The last two decades have seen an increasing reliance on endovascular techniques for both acutely thrombosed aneurysms (catheter-directed thrombolysis) and treatment via stent-graft exclusion.

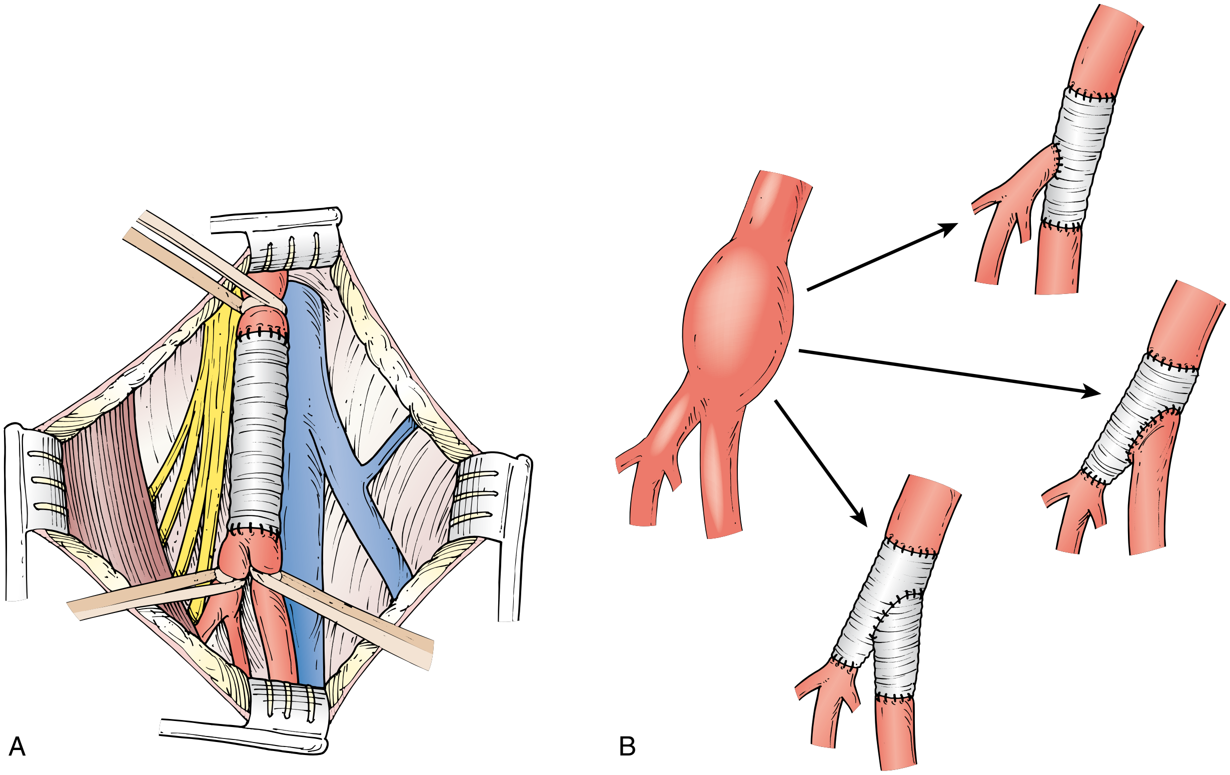

FIGURE 105.10 Surgical repair of an aneurysm confined to the common femoral artery (A) and extending beyond the common femoral artery bifurcation (B). The interposition graft can be placed between the common femoral and either the superficial femoral artery or the profunda femoris artery with reimplantation of the other branch into the side of the graft. If the origin of the artery to be implanted is diseased or not long enough, a short interposition graft can be used. (A, Adapted from Ouriel K, Rutherford RB, eds. *Atlas of Vascular Surgery: Operative Procedure*. Philadelphia: WB Saunders; 1998. B, Adapted from O'Hara P. Treatment of femoral and popliteal artery aneurysms. In: Zelenock GB, Huber TS, Messina LM, et al., eds. *Mastery of Vascular and Endovascular Surgery*. Philadelphia: Lippincott Williams & Wilkins; 2006.)

Incidence, Etiology, and Natural History

The majority of contemporarily described PAAs are true aneurysms and were classically described as degenerative or atherosclerotic in nature. Morphologically, most are fusiform in nature and associated with other cardiovascular risk factors (smoking, age, HTN). There is a strong male predominance, and half of cases are bilateral in nature. PAAs are the most common peripheral aneurysm, accounting for 80% of peripheral aneurysm cases.[45] Up to 75% of patients with PAAs will have aortic ectasia or aneurysm. Although often discovered via a prominent popliteal impulse on physical exam, duplex ultrasound is the standard noninvasive diagnostic modality. All patients with popliteal aneurysm should undergo ultrasound interrogation of the contralateral side and abdominal aorta. Conversely, all aortic aneurysm patients should be screened for PAA. Small popliteal aneurysms may not be palpable (or patient body habitus may preclude accurate exam) and, as such, may present with stigmata of thromboembolism or acute ischemia.

Unlike truncal aneurysms, the natural history of the surgically untreated PAA is that of embolism and thrombosis. Although precise longitudinal data are lacking, approximately a third of PAAs will thrombose within 5 years of diagnosis, with index size and presence of concurrent aortic aneurysm being the most common risk factors for growth or limb-threat event.[46] Rupture is rarely seen in true PAA, and cases of rupture should be considered false aneurysms, likely mycotic in etiology. Traumatic false aneurysm can occur via both blunt force (e.g., knee dislocation with partial transection) and penetrating trauma. Iatrogenic injury with late false aneurysm has also been described after orthopedic surgical procedures.

Large popliteal aneurysms may present with mass effect symptoms, such leg swelling, with or without corresponding deep venous thrombosis or restricted range of motion. Although often obvious via physical exam retrospectively, these cases are often identified at the time of venous duplex for lower extremity swelling. Common differential diagnoses that can be readily ruled out via ultrasound include synovial cyst (Baker cyst) and benign or malignant tumor. CT should be obtained on all significant popliteal aneurysm cases to define anatomy and operative plan (Fig. 105.11; Video 105.1).

Anatomy

The popliteal artery is a dynamic structure, bounded superiorly by the adductor hiatus and inferiorly by the gastrocnemius muscle. The artery sits within the popliteal fossa, which also includes the popliteal vein and tibial and peroneal nerves. The adductor hiatus acts as a proximal fixed point, and, as such, significant torsion, compression, traction, and retraction forces are placed on the proximal popliteal artery during ambulation, which affects both bypass and endoluminal implant considerations.[47] Angiographically, the artery is divided into three segments as follows:

- P1: adductor hiatus to the superior border of the patella
- P2: superior border of the patella to the center of knee articulation
- P3: knee articulation to the origin of the anterior tibial artery

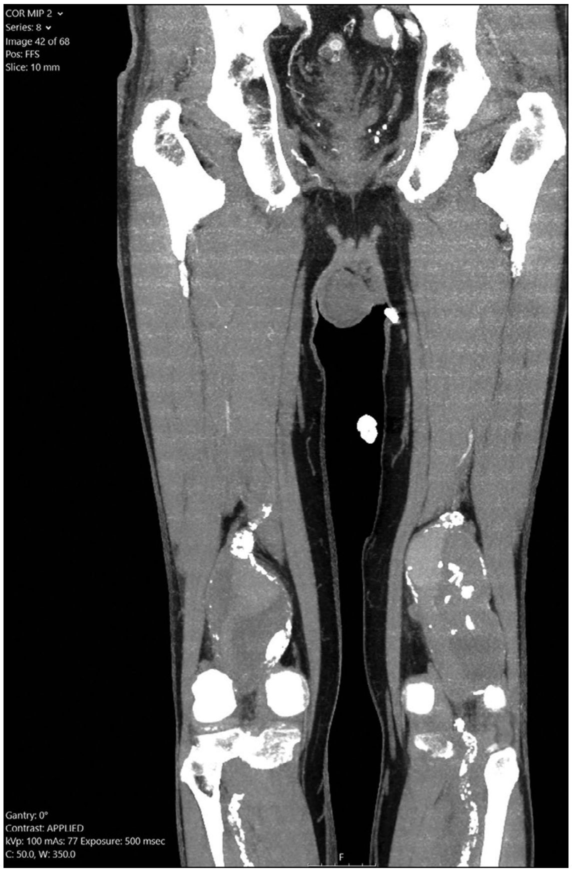

FIGURE 105.11 Computed tomographic coronal reconstruction plan of a patient with large surgically significant bilateral popliteal artery aneurysms (see Video 10.1).

Anatomic variations of the popliteal and its immediate arterial tree are relatively common (approaching 10%–15% of the population), with either hypoplastic tibial arteries or a high origin of the anterior tibial making up most of such cases.[48]

The popliteal artery can be approached via medial, posterior, and lateral exposures, with the former two being the most employed for aneurysmal disease (Table 105.2). Aneurysm extent and surgeon preference dictate the choice of technique, and familiarity with both is a requisite. The authors prefer the posterior approach if the proximal and distal extent of resection are within the anatomic bounds of the adductor hiatus to the tibial arteries.

Operative Indication

- All popliteal aneurysms >20 mm should be repaired.
- Regardless of size, any aneurysm with thrombus should be repaired.
- Any aneurysm associated with signs of ipsilateral thromboembolism should be repaired.
- All pseudoaneurysms should be repaired.

Elective repair of true PAAs is always the goal in physiologically suitable patients with an anticipated good midterm survival and always has a superior limb preservation rate compared with acute revascularization. In cases of unclear etiology, mycotic aneurysm should be considered even in the absence of systemic symptoms.

Surgical Management

Open reconstruction. Bypass with interval ligation of the PAA is the gold standard and should be considered first-line therapy for all patients of good surgical risk. Autologous conduit provides superior primary and assisted patency rates, with a single-segment saphenous vein diameter of 3 mm or greater being ideal. Short saphenous or cephalic vein can also be used as conduit, with expanded PTFE or allograft reserved for no-conduit cases. As with bypass for occlusive disease cases, surgical reconstruction is based on proximal and distal anastomoses being in healthy vessel. Multiple studies have demonstrated that the number of patent runoff vessels correlates with patency rates. Patency rates of saphenous vein bypass in the setting of preserved runoff approximate 90% at 5 years.[49] Patients undergoing open or endovascular reconstruction should be managed with standard cardiovascular risk-reduction medical therapy, including statin-class lipid-lowering drugs, antiplatelet therapy, and angiotensin blockade as indicated.

The PAA should be ligated proximally and distally at the time of open reconstruction to avoid continued pressurization and mass effect–related morbidity. Typically, this is accomplished via complete transection and ligation with a running monofilament suture. Any large geniculate branches arising from the interval segment should be controlled via suture ligature or clip placement to avoid continued flow into the aneurysm sac. Failure to isolate the aneurysm may necessitate reoperation or endovascular secondary intervention. Bypass grafts should be surveilled in the standard fashion via duplex examination with the addition of excluded sac size and flow monitoring.[50]

Posterior approach to the popliteal artery is possible in cases where the extent of aneurysmal disease is restricted to the popliteal fossa (Fig. 105.12). In such cases, the short saphenous vein can be harvested while the patient is in the prone position. Alternately, a popliteal-to-popliteal interposition graft using externally supported prosthetic material yields 80% 2-year primary patency rates and may be preferable to address size mismatch for the end-to-end anastomoses. Comparative data demonstrate superior major adverse limb event rates with open reconstruction compared with endovascular (93% vs.

TABLE 105.2 Operative Approaches to the Popliteal Artery With Surgical Considerations

APPROACH	SURGICAL EXPOSURE	CONSIDERATIONS
Medial	Supine position, slightly flexed knee; proximal incision distal third of thigh lower edge of vastus medialis muscle; distal incision 1 cm inferior to tibia	Popliteal vein will be first structure encountered; midportion of popliteal artery not easily accessible
Posterior	Prone position, S-shaped incision medial to lateral to avoid scar contraction	Tibial nerve, retract laterally; short saphenous vein can be provisionally harvested
Lateral	Supine position, internally rotated leg; proximal exposure between lateral condyle and biceps femoris; distal exposure starting at fibular head	Take care to identify common peroneal nerve

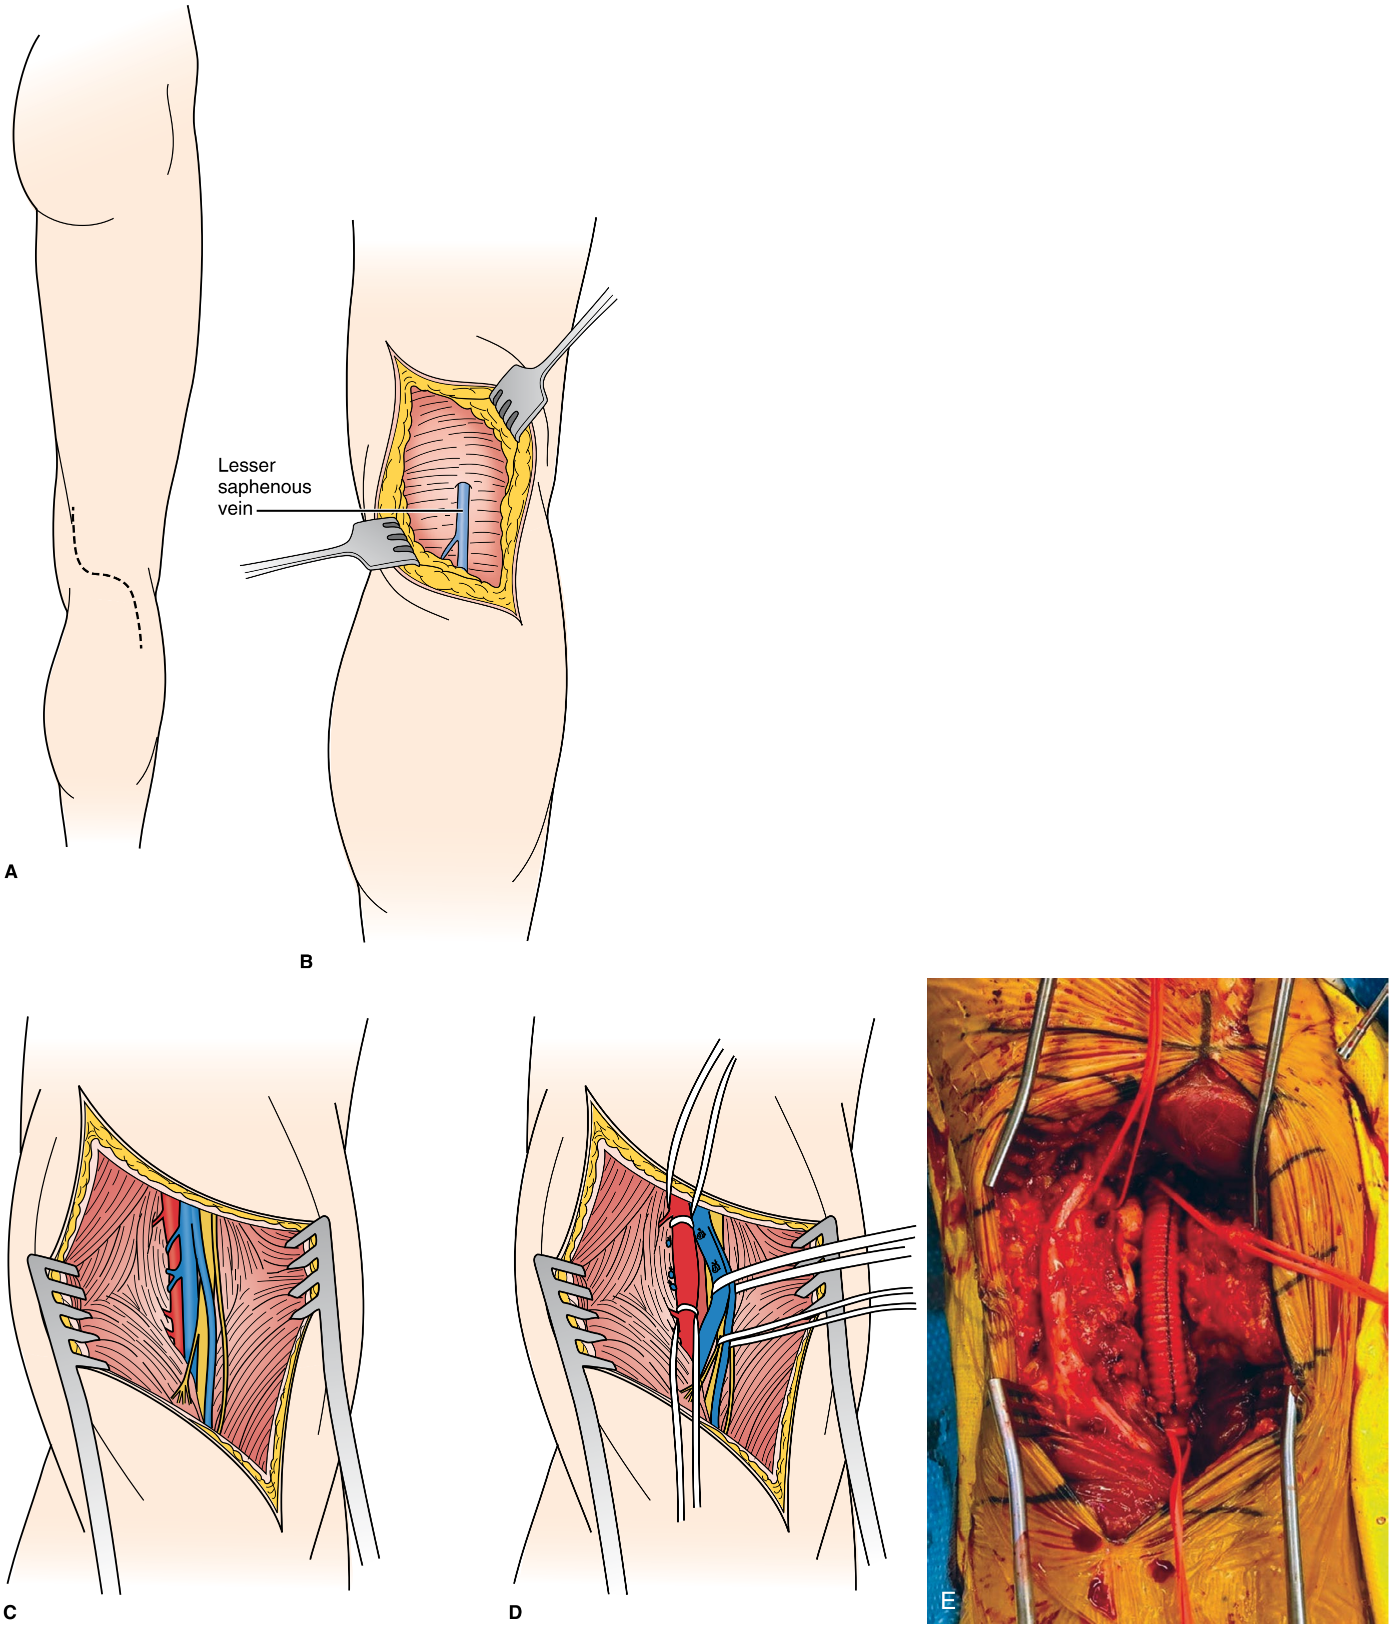

FIGURE 105.12 (A) The incision for the posterior exposure of the popliteal artery is made as a "lazy-S" shape to avoid scar contracture across the knee. Hash marks can be used to aid in skin approximation at case completion. (B) The small (lesser) saphenous vein is identified in the subcutaneous tissue. (C) The deep fascia is incised, and the sural nerve is gently retracted laterally to facilitate the dissection (D) of the popliteal artery from the popliteal vein and the tibial nerve, which lies most superiorly. (E) Intraoperative image after completion of popliteal artery aneurysm repair using synthetic graft. (A–B, From Valentine JR, Wind GG. *Anatomic Exposures in Vascular Surgery*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2003:462, 463. C–D, From Rutherford RB. *Atlas of Vascular Surgery: Basic Techniques and Exposure*. Philadelphia: WB Saunders; 1993:142.)

80% at 1 year), and, as such, bypass should always be considered first line in suitable risk patients with adequate conduit and distal targets.[51]

Endovascular therapy. Endoluminal treatment via stent graft is a viable treatment for patients without suitable autologous conduit and with advanced age, significant comorbidities, and other limb-related factors. The case is predicated on identification of a normal proximal and distal landing zone accounting for a 15% oversizing of the stent graft at the seal sites. Poor runoff, need for extensive coverage past the knee joint, and atherosclerotic burden are associated with decreased primary patency. Intravascular ultrasound is recommended as an adjunct for sizing (luminal diameter, identification of nondiseased landing zone; Fig. 105.13). After stent-graft placement, the proximal and distal seal sites and any graft-graft junction should be balloon angioplastied. If more than one stent graft is required, the smaller-diameter stent should be placed first, and maximal overlap should be used to decrease the risk of type 3 endoleak in this dynamic artery. The literature reports variable patency and adverse limb events after endovascular PAA repair, but most series suggest an 80% 1-year patency rate and higher reintervention rates compared with autologous conduit open bypass. Secondary patency between the two modalities is likely similar. Anatomic and technical correlates of success include number of stent components in the construct, extent of coverage, and runoff score. Patients undergoing stent-based repair should be on the aforementioned best medical therapy, with the addition of dual-antiplatelet therapy unless contraindicated.

From a technical standpoint, the case can be conducted under moderate sedation or monitored anesthesia care. Antegrade access in the common or superficial femoral artery is often possible over the standard retrograde contralateral femoral access. The typical self-expanding stent construct will require a sheath, 8 Fr or larger, so the access is best managed via the preclose technique. After successful angiographic exclusion (Fig. 105.14), patients should be followed with serial duplex ultrasound in the same manner as open bypass patients.[52]

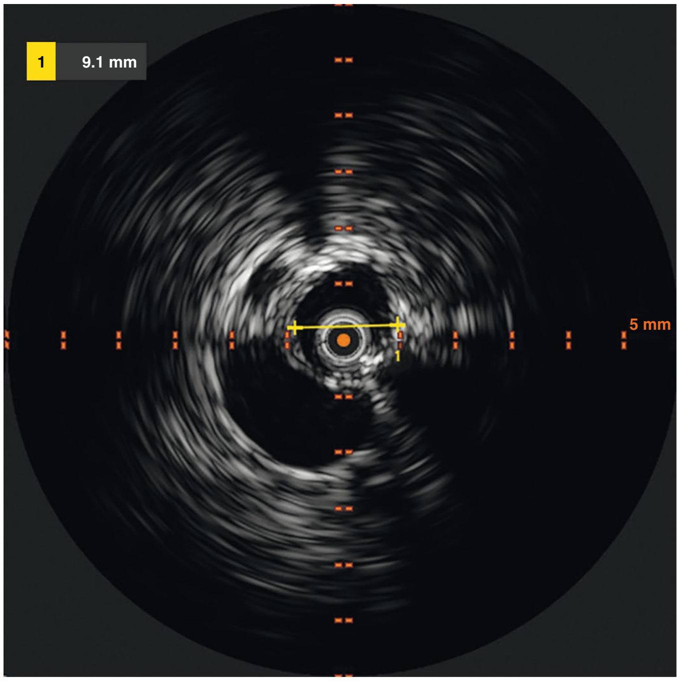

FIGURE 105.13 Intravascular ultrasound of the femoropopliteal segment in a patient undergoing endovascular repair of popliteal artery aneurysm. Examination demonstrates proximal landing zone diameter of 9 mm with a plan to place an 11-mm-diameter self-expanding covered stent.

Acute Limb Ischemia

Because of the thrombogenic nature of PAA and often asymptomatic natural history until presentation, many patients present with acute limb-threat ischemia. Once identified, patients should be immediately anticoagulated and undergo axial or catheter-based imaging to define anatomy. Patients with salvageable extremities (Rutherford grade I or II) should undergo either surgical thromboembolectomy or catheter-based thrombolysis, immediately followed by open or endovascular revascularization as outlined earlier. Surgical thromboembolectomy should be employed in those cases with more immediate limb threat (e.g., sensory deficit, motor deficit with absent pedal signals) because the time required for catheter-based treatment may cause the patient to progress to a nonsalvageable state. Failure to demonstrate a distal bypass target will necessitate amputation, which should be above the knee owing to the fact that the profunda-geniculate collaterals that supply the calf skin and musculature are needed for a below-knee flap. Although exact data are lacking, amputation rates and mortality associated with thrombosed PAA are high, with limb-loss rates ranging from 15% to 70%.[53]

Infrapopliteal and Other Aneurysms

The incidence of tibial and peroneal artery aneurysms is unknown but exceedingly rare. Most commonly, tibial or peroneal artery aneurysms are related to penetrating trauma, fractures, or iatrogenic injury from peripheral endovascular interventions. Aneurysms that present with signs of distal ischemia should be reconstructed. However, simple ligation is often sufficient if other tibial arteries are patent. There are approximately 20 published reports of true anterior tibial artery aneurysms in the literature, which were typically managed with surgical ligation or rarely with endovascular embolization.

Iatrogenic Femoral Aneurysms

Pseudoaneurysms are the result of a transmural arterial defect resulting in extravascular blood flow that is contained by a fiber and sheath. These false aneurysms are typically the result of blunt or penetrating trauma to an artery. Today, most peripheral pseudoaneurysms are iatrogenic and a result of incomplete arterial closure after peripheral access, as required for invasive diagnostic or therapeutic procedures. Pseudoaneurysms have been reported to occur in 0.5% to 9% of arterial access cases.[54] The use of the Seldinger technique under either fluoroscopic or ultrasound guidance is known to reduce the incidence of pseudoaneurysm formation. In addition, large sheath size, patient body habitus, need for anticoagulation, female sex, and hemodialysis have been associated with an increased risk of pseudoaneurysm formation after arterial cannulation.

The feared complication of a pseudoaneurysm is rupture, which can lead to hemorrhagic shock and mortality. Because of this, the anatomic location is critical to note. Pseudoaneurysms of the external iliac artery will rupture into the retroperitoneum. Exsanguination from a CFA pseudoaneurysm is less common. It is rare that a pseudoaneurysm would cause

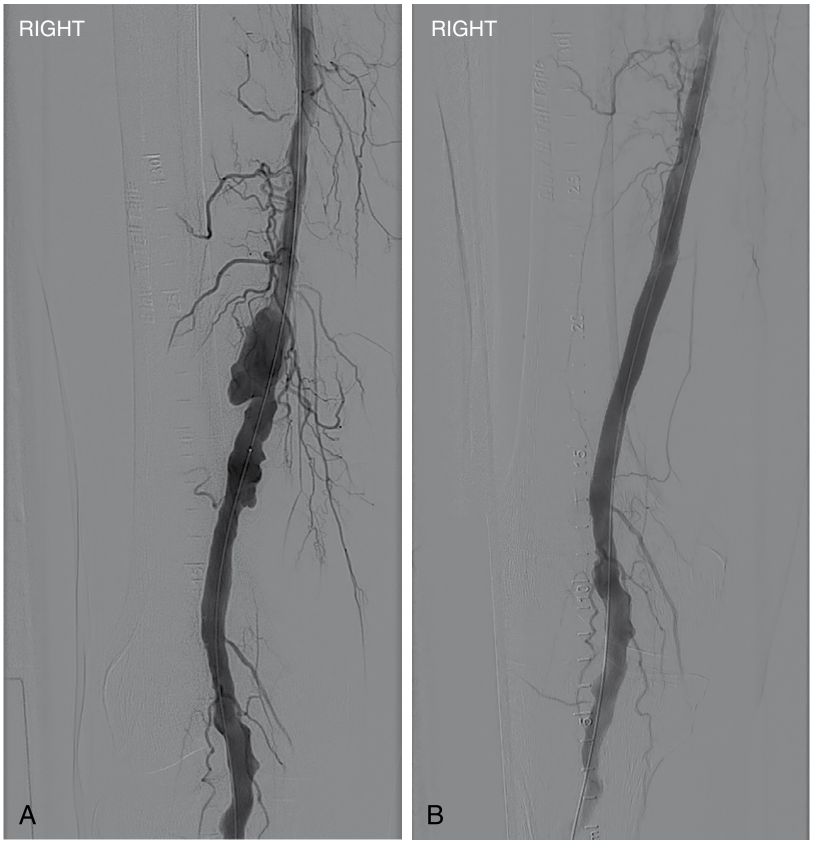

FIGURE 105.14 Angiograph of patient undergoing endovascular popliteal artery aneurysm repair demonstrating initial angiogram with external radiopaque marker (A) to assist with stent selection and successful exclusion of the aneurysm with covered stent and no evidence of endoleak (B).

distal ischemic complications, given that the pathology is a transmural arterial defect. However, the risk for ischemic complications increases as the size of the pseudoaneurysm neck increases.

Diagnosis

Patients with pseudoaneurysms present with a painful pulsatile mass, commonly associated with a hematoma and bruit. Patients can also present with compressive symptoms such as femoral neuropathic pain, pain or paresthesia with hip flexion, or extremity edema. Progressive expansion can lead to skin ischemia and must be addressed to avoid wound formation.

Diagnosis is made with duplex ultrasonography and clinical examination. Continuous to-and-fro flow that is contained will be seen on duplex ultrasound (Fig. 105.15). It also provides important information regarding the anatomy of the false aneurysm sac and its neck. It can be difficult, and occasionally misleading, to diagnose a pseudoaneurysm using CTA alone. Given the static nature of CT imaging, an active hemorrhage can be mistaken for a pseudoaneurysm. This distinction is of critical clinical significance, and clinical evaluation of the patient will distinguish the two diagnoses.

Operative Indications

Ultrasound-guided compressions or thrombin injection:

- Pseudoaneurysms >2 cm
- Pseudoaneurysm diameter growth of >100%
- Persistent pseudoaneurysm after 2 months of observation

Open surgical repair:

- Ruptured pseudoaneurysms (active hemorrhage) require emergent open or endovascular repair.
- Failure or contraindication to ultrasound-guided thrombin injection (broad neck)
- Skin ischemia or necrosis
- Arteriovenous fistula

In most patients, PAAs in the lower extremities can be observed if they are less than 2 to 3 cm in diameter. However, anticoagulation significantly reduces the likelihood of spontaneous thrombosis of the false aneurysm.

Management

Ultrasound-guided compression. Compression of a pseudoaneurysm to induce thrombosis of the aneurysm sac was initially proposed in the early 1990s. This procedure uses duplex ultrasound to visualize the pseudoaneurysm and its neck. Color Doppler should be able to visualize flow within the sac. Pressure is applied to the transducer to compress the aneurysm neck and prevent arterial flow into the aneurysm cavity. The lack of flow should be visualized on color Doppler. Compression is held for 10 to 20 minutes, repeating as needed. The patient should be kept flat in bed for 6 hours and reevaluated with a duplex ultrasound in 24 to 48 hours to evaluate for maintained sac thrombosis. During the procedure, attention must be given to avoid excessive pressure, which can result in compression of the native artery. This can cause arterial thrombosis and subsequent limb ischemia. Case series demonstrate that this technique is successful between 60% and 80% of the time, requiring an

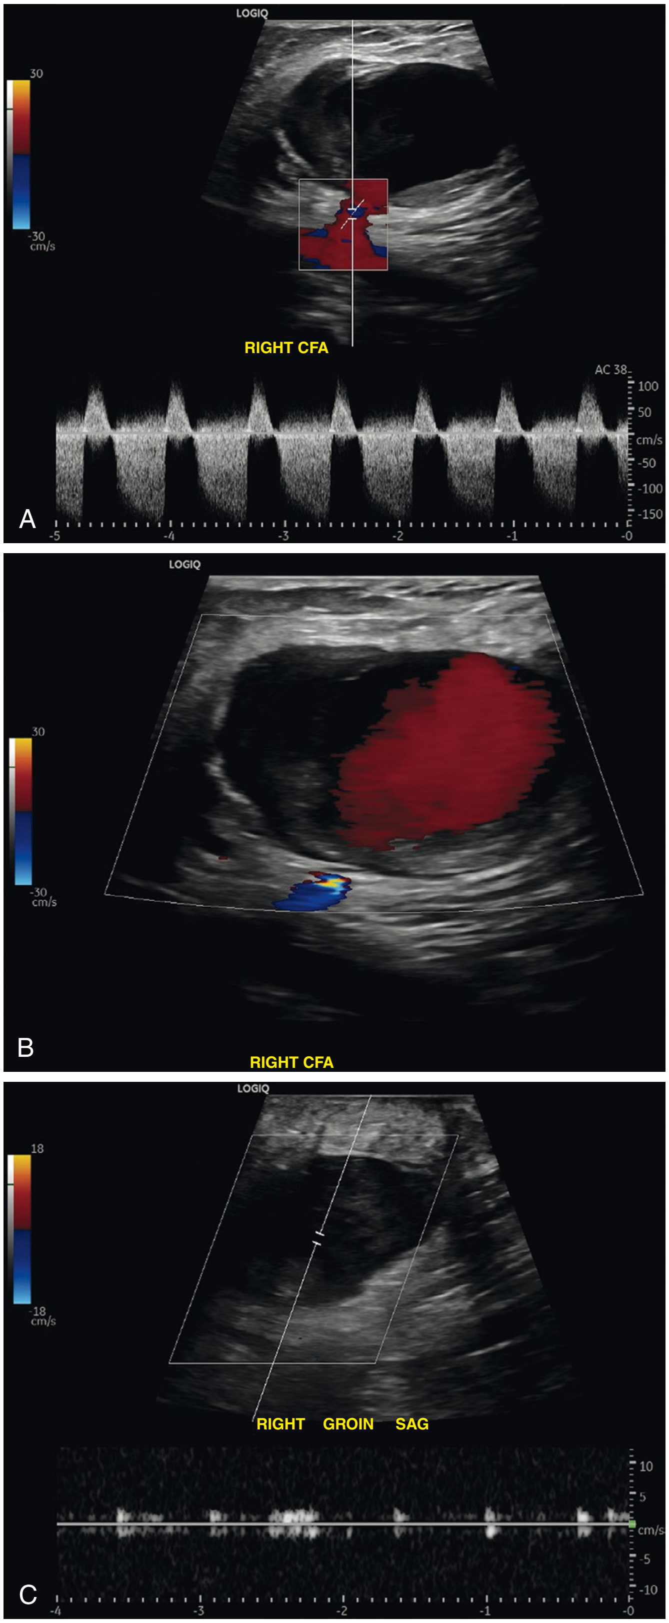

FIGURE 105.15 Duplex ultrasound imaging of large right common femoral artery pseudoaneurysm. Color flow and spectral imaging (A) identified to-and-fro flow through the neck of the pseudoaneurysm, and a ying-yang sign (B) is present within the pseudoaneurysm cavity, both hallmarks of a pseudoaneurysm on duplex ultrasonography. (C) Color flow and spectral imaging do not detect blood flow within the pseudoaneurysm sac after thrombin injection. *CFA,* Common femoral artery; *SAG,* sagittal.

average of 30 to 45 minutes of compression. Patients on anticoagulation have a lower likelihood of successful pseudoaneurysm sac thrombosis. This technique is often not possible for patients with severe pain or large hematomas. Additionally, it should not be performed in patients with acute hemorrhage.

Ultrasound-guided thrombin injection. If ultrasound-guided compression fails or the patient is not a candidate, an ultrasound-guided thrombin injection can be performed. Importantly, the pseudoaneurysm should have a long and narrow neck that is easily identified under ultrasound and easily compressible. A large, short neck increases the risk of the coagulation cascade entering the arterial circulation, inducing intravascular thrombus formation and limb ischemia. Color flow should be seen within the cavity. After administration of local anesthesia and under direct ultrasound visualization, a spinal needle is inserted into the pseudoaneurysm. At this point, blood should be easily aspirated. Approximately 100 to 500 units/mL of thrombin is instilled into the false aneurysm cavity in 0.1-mL increments until thrombosis is visualized by loss of color Doppler signal within the cavity (see Fig. 105.15). Thrombin injection results in immediate clot formation by directly converting fibrinogen into fibrin. This results in effective thrombosis even in patients on therapeutic anticoagulation because the mechanism is downstream of the effects of warfarin, heparin, and new oral anticoagulants. It is critically important to maintain visualization of the aneurysm cavity and immediately stop the injunction once thrombosis has been achieved. Continued injection after thrombosis of the false aneurysm cavity can lead to intravascular thrombin injection and arterial thrombosis. Embolization of thrombus into the distal circulation occurs in approximately 2% to 4% of cases. A complete pulse examination should be obtained before and after each procedure to identify this complication.

Open reconstruction. Open surgical repair should be performed for ruptured pseudoaneurysms, patients presenting with skin symptoms, pseudoaneurysms associated with arteriovenous fistula, or pseudoaneurysms that have failed to thrombose after all ultrasound-guided therapy. Surgical management should follow all principles of vascular surgery, including proximal and distal control, followed by arterial reconstruction. In the acute setting of rupture and hemodynamic instability, manual compression at the side of bleeding should be applied immediately, followed by surgical vascular control. Direct repair of the arterial injury with Prolene suture is effective for small defects. For larger injuries, patch angioplasty repair can be performed. Occasionally, the size of the pseudoaneurysm and subsequent fibrin sheath will envelop the native artery, making dissection difficult. In this scenario, resection of a small arterial segment with interposition graft reconstruction can be performed. Autologous greater saphenous vein (GSV) is preferred; however, the femoral artery diameter is typically much larger than the GSV. In this setting, a short segment of Dacron can be used.

MYCOTIC ANEURYSMS

Although outside the scope of this chapter, myotic aneurysms warrant mention. In brief, all mycotic aneurysms are pseudoaneurysms and mandate operative reconstruction with autologous or biologic conduit. Various techniques are described across all arterial beds. *Staphylococcus* spp. represent the most common isolate. When discovered, all patients with infectious etiology aneurysm should undergo parenteral antibiotic therapy and rapid imaging workup, followed by surgical therapy.

ACUTE MESENTERIC ISCHEMIA

Epidemiology

Mesenteric ischemia was first described by Chienne in 1869 and remains challenging to diagnose and treat in the present day despite medical and surgical advancements.[1] The first intestinal resection and reanastomosis was performed by Elliot in 1895. In 1951, Klass performed the first superior mesenteric artery (SMA) embolectomy, and in 1957 Shaw and Maynard performed the first embolectomy to be considered successful without requiring subsequent bowel resection. In 1980, endovascular treatment of mesenteric disease was introduced to practice and represents a major advance in the distinct ability for surgical techniques to care for these patients. Today, acute mesenteric ischemia (AMI) accounts for less than 1 per 100,000 hospital admissions in the United States and less than 2% of all admissions for gastrointestinal disorders.[2]

Incidence of AMI increases with age and nearly doubles with each 5-year interval above the age of 70.[3] It is typically seen in patients with multiple comorbidities with a threefold increase in females compared with males.[4] AMI is the final common pathway for several clinical scenarios, each of which has its own characteristic epidemiology, including mesenteric arterial thromboembolic disease, mesenteric venous thrombosis (MVT), and nonocclusive mesenteric ischemia (NOMI).[5] Risk factors include those at risk for thrombosis or embolus (atherosclerosis, atrial fibrillation/flutter, recent myocardial infarction [MI], congestive heart failure) or history of chronic mesenteric ischemia (CMI). Those at risk for NOMI are patients that have critically ill conditions and are in shock from alternative sources, with postoperative cardiac surgery and hemodialysis patients at highest risk.

Over the years, studies have shown a dramatic decrease in mortality rates from 1999–2010, with open repair showing the most dramatic improvement over time from 43% to 33%.[6] In-hospital mortality has also decreased following endovascular revascularizations, falling from 20% to 15%. Despite technical advancements over time, overall mortality remains high at 17% to 21% among patients requiring intervention.[4,7]

Pathophysiology

Embolic

AMI pathophysiology is divided into embolic, thrombotic, and nonocclusive categories. Arterial embolism is the most common cause, comprising about 40% to 50% of cases.[8,9] Patients presenting with mesenteric ischemia secondary to an embolic event typically have a history of preceding embolic event, most commonly arising from a cardiac source such as atrial fibrillation/flutter, ventricular thrombi secondary to low ejection fraction from recent MI or heart failure, valvular disease, endocarditis, and/or aortic aneurysms with associated mural thrombi. As high as 68% of patients have simultaneous embolic events in other vascular beds (cerebrovascular, peripheral).[10,11]

The SMA is the second branch of the abdominal aorta, and its branches include the inferior anterior and posterior pancreaticoduodenal arteries, the middle colic artery, right colic artery, ileocolic artery, and jejunal and ileal branches, respectively. Given the oblique angle of the SMA origin off the aorta, thromboemboli preferentially will lodge in this visceral vessel. The SMA tapers just beyond the first few jejunal branches; thus, emboli typically settle more proximally. About 50% of embolic events occur just distal to the middle colic artery and 15% may lodge at the SMA origin.[12,13] The middle colic artery terminates into a right and left branch and anastomoses with the branches of the right and left colic arteries and contributes to the formation of the marginal artery of Drummond. The right branch supplies the upper segment of the ascending colon and hepatic flexure, and the left branch supplies the proximal two-thirds of the transverse colon. Embolic events to the SMA proximal to the middle colic artery cause a classic formation of ischemia that typically spares these portions of the bowel. Embolization to the celiac artery occurs more rarely, and normally becomes symptomatic in patients with preexisting SMA disease. Mortality for thromboembolic events to the SMA without intervention is high, averaging 54%.

Thrombosis

Arterial thrombosis is the second most common cause of AMI averaging 20% to 35%. Typically, most patients presenting with thrombotic etiology of AMI have a prior history of CMI from preexisting chronic lesions. In situ thrombosis of chronic lesions is most common, and patients with peripheral vascular disease have an incidence of AMI that may be as high as 27% in some studies.[14] In acute-on-chronic ischemia, presentation of bowel ischemia may be delayed given preexisting collateral channels that can maintain perfusion until events such as small emboli or episodes of hypotension result in occlusion of the significantly stenosed vessel. Other causes of thrombosis include hypercoagulable syndromes (factor V Leiden, antiphospholipid syndrome, prothrombin gene mutations, antithrombin III syndrome, protein C/S deficiency), extensions of aortic dissection resulting in compression and inhibition of flow through the true lumen, and thrombotic complications of previous mesenteric interventions (in-stent or graft thrombosis). Thrombosis most commonly affects the SMA, and the location is typically within 2 cm of the vessel origin. Given the proximity of occlusion, mortality rates without intervention are higher for thrombosis than emboli (77%), likely secondary to involvement of larger segments of bowel. Thrombosis of the celiac artery can also be clinically significant, normally in the setting of preexisting SMA disease.

Nonocclusive Mesenteric Ischemia

NOMI is a clinical syndrome that is the result of a combination of pathophysiologic phenomena including mesenteric vasoconstriction, intestinal hypoxemia, reperfusion injury, increased intestinal metabolic demand, and infection.[15] NOMI comprises about 20% of AMI cases and most frequently affects the SMA. A key aspect in the development of NOMI is a low flow state with or without prior mesenteric vessel stenosis. Hence, this cause of mesenteric ischemia is typically seen in critically ill patients. Patients with severe cardiac failure and recent cardiac surgery and critically ill hemodialysis patients are at greatest risk.[16] Vasoactive pressors such as epinephrine, norepinephrine, and vasopressin have also been associated with the development of NOMI.[17] Although mesenteric stenosis may be present, its absence in many cases points to a vasospastic mechanism in the critically ill patient that attempts to prioritize cerebral and cardiac perfusion at the expense of visceral perfusion. NOMI carries the highest mortality rate of all AMI causes, partly due to the nature of the underlying illness.

Clinical Evaluation

History and Physical Presentation

AMI leads to severe inflammation that often presents initially with vague diffuse abdominal pain that is “out of proportion” to examination. Other symptoms can include nausea, vomiting, diarrhea, and melena. Once transmural ischemia occurs the patient will exhibit signs of peritoneal irritation leading to guarding and rebound tenderness. If full necrosis of the bowel occurs, the patient may rapidly decline and present with septic shock including tachycardia, hypotension, altered mental status, and fever.

Acute onset and rapid clinical decline are most pronounced in patients with embolic etiology secondary to the lack of robust collateral circulation and perfusion. Those with thrombotic etiology may have a more insidious onset as a result of well-formed collateral circulation. Some may even present a subacute phase that can last from days to weeks with symptoms ranging from mild abdominal pain, diarrhea, nausea, vomiting, or gastrointestinal bleeding. Patients with NOMI have a wide range of clinical presentation and are typically presenting with concurrent organ failure. They may or may not have abdominal pain and often have findings consistent with systemic sepsis, laboratory abnormalities, and abdominal distention.

The differential diagnosis for abdominal pain is broad, including appendicitis, diverticulitis, cholecystitis, pancreatitis, and bowel obstructions. Studies have shown that delays in diagnosis lead to significant decrease in survival from 50% to 30% when the diagnosis of SMA embolism is made more than 24 hours from symptom onset.[13] Thus, a high index of suspicion is required to prevent delays in diagnosis. In modern surgical care, surgical consultation is often already preceded by cross-sectional imaging performed in the emergency department.

Laboratory Findings

Abnormalities in laboratory values are adjuncts to the diagnosis of AMI but do not definitively confirm or dismiss the diagnosis. Initial lab values can be normal but may show abnormalities such as leukocytosis (>15,000 with neutrophilic left shift), metabolic acidosis, and elevated lactate. D-dimer is an early sensitive marker but is not specific with high false-positive rates. Elevations in levels of serum amylase, creatine kinase, and aminotransferases may be seen but lack sufficient sensitivity and specificity. Novel, specific serologic markers are currently being studied (urinary and plasma intestinal fatty acid-binding proteins [iFABP]) to facilitate earlier detection of AMI but are not currently used in routine practice.[18,19]

Diagnostic Evidence

In modern practice, the single best imaging modality to confirm the diagnosis of AMI is CT angiography (CTA), with a sensitivity and specificity of 93% and 96%, respectively.[20] Although previous practice has denoted the use of diagnostic angiography as the gold standard for diagnostic evaluation, the widespread availability of high-quality CT scanners nationwide and diagnostic accuracy has made CTA the imaging modality of choice. CTA can assess for filling defects in the visceral vessels, and when performed with both an arterial and delayed venous phase (biphasic CTA) can also allow for evaluation of the portal venous system and bowel wall perfusion (Fig. 106.1). Characteristic findings of intestinal ischemia include bowel wall thickening and mucosal wall enhancement, pneumatosis, and portal venous gas. MVT, another source of visceral ischemia when severe, can also be assessed using CTA. Although CTA is useful for the diagnosis of occlusive mesenteric ischemia, its use for diagnosis of nonocclusive disease is less reliable.

Plain radiographs are usually unrevealing unless significant intestinal necrosis has occurred. Some abnormalities seen on radiographs in the late stages of ischemia include ileus, thumbprinting (due to submucosal hemorrhage and bowel wall edema), pneumatosis linearis, or portal venous gas. Doppler ultrasonography is a valuable tool for assessment of visceral vessels and detection of

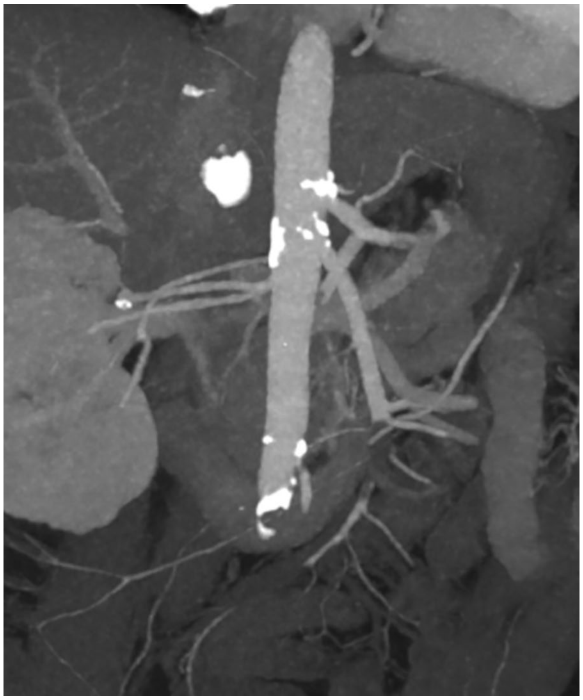

FIGURE 106.1 Anterior-posterior and lateral CT. A reconstruction of acute embolus to the mid superior mesenteric artery.

high-grade stenoses in the SMA and celiac artery for CMI. However, in the acute setting this imaging modality is not considered reliable due to its limitation to evaluate the visceral vessels and emboli past the origin and assess for signs of intestinal ischemia. Magnetic resonance angiography (MRA) is another imaging modality with high diagnostic accuracy, but it is less readily available and more time consuming than CTA, making it less favorable in the acute setting.

Management

Medical Treatment

Patients presenting with AMI warrant immediate medical management. This includes establishment of IV access with crystalloid fluid resuscitation, hemodynamic monitoring, and correction of electrolyte abnormalities. Systemic anticoagulation should be initiated promptly upon diagnosis to prevent further propagation of thrombus. Additionally, administration of broad-spectrum IV antibiotics should be given to treat potential translocation of bacteria in the setting of ischemic bowel.[21] Vasopressors should be avoided, if possible. If vasopressors are necessary in the setting of hypotension refractory to fluid resuscitation, then those with less splanchnic vasoconstriction should be prioritized including dobutamine, milrinone, and low-dose dopamine.[22] Although these initial managements are crucial, it should be done in congruency with surgical planning and should not delay revascularization.

Medical management of NOMI includes correction of the underlying cause such as improving cardiac output, weaning vasopressors if able, and supportive care. Intraarterial infusion of vasodilators such as papaverine, nitroglycerin, or prostaglandin analogues selectively increase splanchnic blood flow and have been described for treatment of NOMI in small case series. However, no large or well-controlled clinical trials exist to support this treatment as standard practice.[23,24]

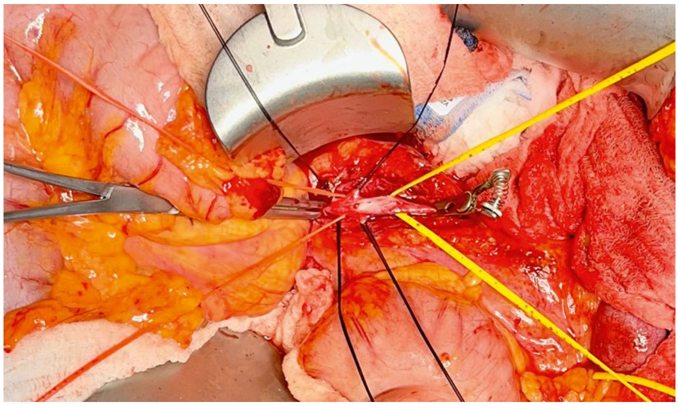

FIGURE 106.2 Longitudinal arteriotomy made after dissection of the mid superior mesenteric artery in the root of the mesentery with control of the side branches to allow for embolectomy and subsequent patch repair.

Revascularization

Prompt revascularization via thromboembolectomy and assessment of the bowel is the standard technique for embolic disease. Embolectomy of the SMA requires anterior exposure of the vessel. This is achieved by lifting the omentum and transverse colon cephalad and mobilizing the small intestine to the patient's right. At the base of the transverse mesocolon, a horizontal incision is made to expose the anterior portion of the SMA. Venous tributaries, small lymphatics, and autonomic nerve fibers require ligation to facilitate arterial exposure, keeping in mind that the superior mesenteric vein lies left to the artery. For more proximal control, the inferior pancreatic border and splenic vein (SV) may require mobilization. The SMA is exposed and controlled proximal to the middle colic artery, and after systemic heparinization the artery is opened transversely. More recently, we have preferred longitudinal arteriotomy for the ability to either patch the vessel or use as a bypass target (Fig. 106.2).

The proximal SMA is vented to allow any clot to spontaneously evacuate. A Fogarty balloon thromboembolectomy catheter should be performed with a 3-Fr or 4-Fr catheter, and if distal vascular embolectomy is required, then the catheter should be down-sized to a 2 Fr or 3 Fr. The balloon should be inflated with heparinized saline as the catheter is withdrawn and repeated until free of thrombus burden. Once cleared of thrombus, the arteriotomy can be repaired primarily with 5-0 or 6-0 monofilament suture in an interrupted fashion. A venous or bovine patch may be necessary in a diminutive or heavily plaque-ridden vessel. If distal thrombus was not removed, the surgeon can consider direct infusion of 0.5 to 1 mg of tissue plasminogen factor (tPA) into the vessel.

In AMI secondary to thrombosis, a bypass is often required for successful revascularization as often these vessels contain proximal or long segments of plaque burden that may prevent adequate revascularization from embolectomy or stenting alone. There are multiple arrangements for graft orientation and type of conduit and each option should be decided based on preoperative imaging and individual patient anatomy as well as their overall physiologic state. A retrograde bypass off the right common iliac artery (CIA) oriented in a "lazy C" configuration with synthetic graft is one option frequently favored in the emergent setting and critically ill patient. This option avoids significant hemodynamic shifts by negating the need for aortic cross-clamping. The lateral portion of the SMA is exposed cephalad to the fourth portion of the duodenum by opening the peritoneum adjacent to the duodenum with full exposure of the distal aorta and iliac artery.[21] The graft of choice is typically 6 to 8 mm externally enforced polytetrafluoroethylene (PTFE) or Dacron given their resistance to kinking and appropriate size match. However, in cases of gross contamination from spillage of necrotic bowel, an autologous vein is preferred. In patients where the right common iliac is not suitable for bypass, then the left CIA or infrarenal aorta may be considered. In patients where there is no suitable anatomy for retrograde bypass (distal inflow heavily calcified or aneurysmal), then antegrade bypass can be considered. However, this exposure increases operative times, technical complexity, and results in significant hemodynamic shifts with supraceliac aortic clamping.

Retrograde open mesenteric stenting (ROMS) is a hybrid procedure for SMA thrombosis that has been shown to be an efficient and less invasive revascularization option. The SMA is exposed similarly to an embolectomy exposure and is cannulated in retrograde fashion. The SMA is then stented using endovascular wires, catheters, and fluoroscopy imaging to facilitate appropriate stent placement. This technique avoids the need for aortic cross-clamping, prosthetic conduit, and technical complexity associated with further aortic exposure. A multicenter study from the Vascular Low Frequency Disease Consortium has shown this technique to have a success rate of 98% and primary and secondary patency of 76% and 90%, respectively, at 2 years.[25]

After revascularization, the bowel should be thoroughly assessed. In some instances, bowel resection may be performed first. These instances include patients with bowel perforation or free air on prior imaging. Additionally, those suspected of having complete bowel necrosis should undergo abdominal exploration as revascularization is not warranted in these cases and is usually a nonsurvivable scenario.

In patients who have undergone open revascularization, the bowel should be assessed for viability. Bowel that is evidently necrotic should undergo resection and left in discontinuity. Aggressive efforts to resect bowel with questionable viability should be avoided. A temporary abdominal closure device should then be placed with reexploration in 24 to 36 hours. A second look allows for preservation of maximal bowel length as it gives segments with questionable viability to recover once blood flow has been restored. In patients who underwent endovascular revascularization, a laparoscopic approach to assess the bowel can be undertaken by a skilled surgeon who feels comfortable with this approach.

In contemporary practice, not all patients undergo open abdominal revascularization or exploration. Endovascular treatment of AMI has steadily increased since the early 2000s and recent studies indicate improved morbidity and mortality with this strategy. Endovascular management of AMI includes pharmacomechanical embolectomy, angioplasty, intraarterial thrombolysis, and stenting. Exclusive endovascular treatments for AMI should only be considered in patients without evidence of bowel ischemia. This technique negates the need for laparotomy and has been shown to reduce hospital stay and need for postoperative parenteral nutrition in patients who were appropriately chosen for endovascular therapy alone.[21]

MESENTERIC ARTERY DISSECTION

Mesenteric artery dissection most often occurs as a complication following abdominal aortic dissection. Spontaneous isolated mesenteric artery dissection (SIMAD) conversely is very rare. Most cases of IMAD involve the SMA (SISMAD) and incidence is reported around 0.06%. A higher incidence is reported in males of Korean, Japanese, and Chinese descent suggesting a genetic predisposition. Etiology is most commonly idiopathic, but other possible causes include fibromuscular dysplasia, segmental arterial mediolysis, cystic medial necrosis, Behcet disease, trauma, heavy weightlifting, and pregnancy.[26–28] Dissection location normally occurs 1 to 3 cm from the SMA ostium, likely due to elevated shear stress at the vessel transition point from a fixed retropancreatic position with an acute turn into a mobile mesenteric root. Interestingly, hypertension is not clearly associated as a risk factor for SISMAD.

Clinical presentation can vary from patients who are completely asymptomatic and is found incidentally on imaging or they can present with severe symptoms. The pain associated with SISMAD is typically isolated to the epigastric area and can radiate to the back and is likely due to irritation of the visceral nerve plexus due to inflammation from arterial dissection that usually resolves with time. Patients presenting with pain out of proportion to examination, however, are suggestive of visceral ischemia. Diagnostic workup is similar to that of AMI, including laboratory tests that may or may not be abnormal. CTA is the imaging modality of choice for diagnosis, which can assess for dissection flaps, false lumens, reentry tears, thrombus, intramural hematomas, aneurysm formation, and rupture.

SISMAD does not have a well-studied treatment algorithm in place given its low prevalence; however, general treatment guidelines have been developed based on the morphology of the dissection as well as the patient's presenting symptoms. In general, those in which a dissection was found incidentally and remain completely asymptomatic can be managed conservatively with antiplatelet therapy. If there is significant luminal compromise on imaging or mild symptoms, then some authors have suggested anticoagulation. However, the role for antiplatelets and anticoagulation has not been well defined.

For symptomatic patients without signs of ischemia, the initial management includes bowel rest and observation with serial abdominal examinations. Additionally, most are started on a heparin drip, although its role is also not well defined in the symptomatic group. If pain worsens or persists despite bowel rest and anticoagulation, then interventional treatment should be considered. Most patients who have persistent abdominal pain undergo arterial stenting as the primary treatment modality. Endovascular stenting eliminates stenosis caused by the false lumen and stabilizes the arterial wall to prevent future aneurysmal degeneration. There are no treatment guidelines that exist for stenting. However, some have suggested that stenosis of the SMA greater than 80% or dilation to more than 2 cm are indications for primary stenting.[29] Others have observed radiographic and symptomatic improvement with conservative management alone.[30] Patients who present with rupture from the dissection or advanced bowel ischemia are better candidates for open surgery than endovascular approaches. Direct repair of the arterial dissection can be performed, but in the setting of threatened visceral organs further repair is necessary. Surgical options include aortovisceral bypass, extraanatomic bypass, and intimectomy/fenestration with patch repair. Arterial inflow of choice for extraanatomic bypass is often the gastroepiploic or hepatic artery.

No contemporary guidelines exist for the surveillance of mesenteric arterial dissections. However, most surgeons perform some routine follow-up. CTA is the imaging modality of choice, but duplex ultrasound (DUS) can also be considered when anatomically appropriate. Surveillance is done to monitor for the development of an aneurysm from arterial degeneration secondary to the dissection. True incidence of aneurysmal formation is not known, but there are reports in the literature of this phenomenon.[31] However, most dissections undergo remodeling rather than aneurysm formation. A single-center study has shown that 41% of SISMAD treated conservatively had improvement on surveillance imaging and 15% of patients had complete remodeling of the SMA.[32] Thus, a majority of patients presenting with IMAD can be treated conservatively.

CHRONIC MESENTERIC ISCHEMIA

Epidemiology

CMI is a rare medical condition caused by the imbalance between the blood supply and physiologic demand within the gastrointestinal tract. The symptoms associated with CMI include postprandial abdominal pain, which often results in "food fear" and weight loss. Currently in the United States, CMI accounts for less than 1 per 100,000 hospital admissions, although reported incidence has steadily increased over the past two decades. The most common cause of CMI includes atherosclerosis resulting in hemodynamically significant stenosis or occlusion of mesenteric vasculature including the celiac axis (CA), SMA, and/or inferior mesenteric artery (IMA). CMI affects patients in their sixth and seventh decade of life and is three times more common in female patients. Over the past 50 years, revascularization techniques including both open and minimally invasive endovascular technologies have evolved for the treatment of CMI.[33,34]

Pathophysiology

The primary circulation to the small and large bowel includes the CA, SMA, and IMA. However, robust collateral pathways exist for the purposes of maintaining mesenteric perfusion. The arc of Riolan is a collateral pathway between the left colic artery, a branch of the IMA, and the middle colic artery, a branch of the SMA. The pancreaticoduodenal arcade, or arc of Buhler, and gastroduodenal arteries allow for collateralization between the CA and SMA (Fig. 106.3). Under fasting conditions, approximately 20% to 25% of cardiac output is delivered to mesenteric circulation, increasing to nearly 35% to 40% following mealtime. Postprandial intestinal hyperemia is the physiologic, vasodilatory response to food within the lumen of the gastrointestinal tract. Based on complex neural, humoral, and paracrine pathways, the magnitude and duration of the hyperemia is determined by the composition of the meal. Compared with carbohydrate-based meals, lipid and protein-based intake elicits a higher magnitude (25%–200%) and longer duration (3–7 hours) of intestinal hyperemia.[35,36]

Atherosclerotic disease within mesenteric vasculature, also known as mesenteric artery occlusive disease (MAOD) or mesenteric artery stenosis (MAS), is estimated to affect up to 10% of the elderly patient population. However, only a small portion of patients with MAOD will present with symptomatic CMI given the extensive, collateral network within the splanchnic circulation. The degree of atherosclerotic burden and number of diseased mesenteric vessels is often positively correlated with symptomatology. Patients with diffuse atherosclerotic disease, high-grade stenosis greater than 70%, or occlusion of at least two mesenteric vessels increases the risk of progression to symptomatic CMI.[37] Common risk factors for the development of atherosclerotic disease include hypertension, hyperlipidemia, diabetes, and tobacco use. Atherosclerotic disease is the most common cause of CMI, accounting for greater than 90% of all cases. Other etiologies include fibromuscular dysplasia, Takayasu arteritis, Buerger disease, radiation, neurofibromatosis, autoimmune arteritis, aortic dissection, aortic coarctation, mesenteric venous stenosis or occlusion, and drug-induced arteriopathy.[37]

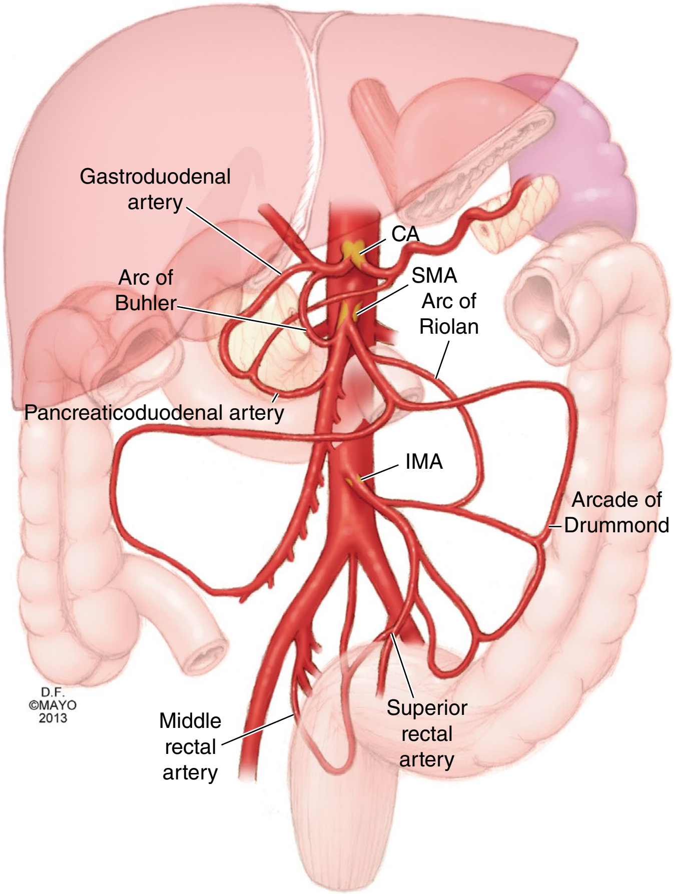

FIGURE 106.3 Schematic representation of mesenteric circulation. Collateral pathways include arc of Riolan (connecting left colic artery arising from the inferior mesenteric artery *[IMA]* and middle colic artery arising from the superior mesenteric artery *[SMA]*) and the arc of Buhler (or pancreaticoduodenal arcade connect the celiac axis *[CA]* and SMA).

Clinical Evaluation

Patient Presentation

Patients with symptomatic CMI are older, usually in their sixth or seventh decade of life, with a median age of onset of 67 years. Patients with a diagnosis of CMI are three times more likely to be female and have long-standing risk factors for atherosclerotic disease as previously described. Symptoms include postprandial pain occurring within 15 minutes and lasting up to 7 hours following meals, resulting in food fear and unintentional weight loss. Patients can experience abdominal pain of varying quality and location, postprandial nausea, vomiting, and diarrhea.[38]

Although adjustments in eating habits can attenuate symptoms, patients with significant weight loss can subsequently experience malnutrition and cachexia. Physical examination findings are often nonspecific. Therefore, a complete vascular examination including peripheral pulse examination is required due to the increased prevalence of concomitant disease in other vascular beds. Given the advanced age of onset and likelihood of medical comorbidities, the differential diagnosis for patients with CMI is broad, including but not limited to acute cholecystitis, acute gastritis, AMI, appendicitis, biliary obstruction, cholangitis, diverticulitis, pancreatitis, and intraabdominal malignancies. Baseline laboratory tests should include complete blood count, comprehensive metabolic panel (including hepatic function tests), and nutritional assessments (C-reactive protein [CRP], prealbumin, vitamin C/D, and zinc).[38]

Imaging and Diagnostics

The Society for Vascular Surgery (SVS) recommends mesenteric DUS as the preferred screening test for MAOD. A diagnosis of CMI is considered in patients with greater than 70% stenosis within the CA and/or SMA, and the presence of corresponding symptomatology. A peak systolic velocity of 200 cm/s and 275 cm/s is consistent with greater than 70% stenosis within the CA and SMA, respectively. CTA is now considered the preferred imaging modality for MAOD. CTA imaging allows for detailed anatomic evaluation of mesenteric vasculature required for preoperative planning.[39] Other imaging alternatives include contrast arteriography, previously considered the gold standard diagnostic modality, or MRA. Other adjunctive imaging modalities, including esophagogastroduodenoscopy (EGD), colonoscopy, abdominal ultrasound, and abdominal CT, can be used during multidisciplinary evaluation. All patients with abdominal pain and weight loss should undergo expedited workup for gastrointestinal and intraabdominal malignancies.[39]

Management

Indications for Revascularization

The SVS recommends treatment for patients with CMI to reverse presenting symptoms (weight loss, food fear, postprandial pain), prevent the development of AMI, and improve overall quality of life. For both symptomatic and asymptomatic patient populations, a shared decision-making approach should be prioritized when discussing revascularization as a treatment option. However, asymptomatic patients can also be considered for annual surveillance with mesenteric duplex and interval clinical evaluation.[39]

Several single-center retrospective studies have suggested that prophylactic endovascular intervention can be discussed for asymptomatic patients with greater than 50% to 70% stenosis of the SMA, and CA or IMA. Asymptomatic patients with three-vessel mesenteric disease have demonstrated increased risk of subsequent, life-threatening AMI.[40] Other indications for revascularization include patients undergoing surgery for concomitant mesenteric artery aneurysms, or open aortic reconstruction with involvement of the SMA. The primary target for revascularization is the SMA. The CA or IMA are secondary targets for revascularization and may be intervened upon to aid in symptom relief when SMA intervention is prohibitive or technically difficult.[41]

Medical Management and Preoperative Evaluation

All patients with underlying MAOD should undergo medical optimization and obtain a baseline CTA to delineate critical vascular anatomy required for revascularization. Other imaging used for preoperative risk stratifications includes echocardiogram, pulmonary function testing, and lower extremity arterial and carotid ultrasound. A wholistic review of individual factors including concomitant medical comorbidities, nutritional status, and patient anatomy should be considered before revascularization. Medical therapy for those treated with and without intervention should include antiplatelet agents, cholesterol-lowering medication, β-blockers, and tobacco cessation.[40] For symptomatic patients, total parenteral nutrition (TPN) is not considered a long-term, acceptable alternative to revascularization per SVS recommendations. The risk of complications including catheter-associated infections, bowel infarction, and liver failure are considered prohibitive for patients on long-term parenteral nutrition. However, TPN may be required perioperatively for nutritional optimization when undergoing revascularization.[42]

Endovascular Revascularization

General Endovascular Principles

The SVS recommends endovascular revascularization as the initial treatment to restore antegrade flow for patients with CMI and suitable mesenteric lesions. The SMA is considered the primary target for revascularization, whereas the CA and IMA are secondary targets. Mesenteric angioplasty and stenting have been widely adopted and largely replaced open surgical repair as first-line treatment for CMI over the past 20 years.[43] This is in large part due to lower early postoperative morbidity and mortality.[44] A recent meta-analysis including 16 retrospective studies with 1368 target vessels demonstrated high technical successful (95%) and low 30-day mortality (2%) for CMI patients treated with endovascular therapy. However, symptom recurrence and reintervention were observed in approximately 25% of patients.[45] Angioplasty with concomitant stenting is recommended given the increased risk for elastic recoil and subsequent restenosis. Literature has demonstrated that intervention of multiple mesenteric vessels can result in prolonged procedure time without significant differences in symptom relief. In the setting of two- and three-vessel disease, recanalization and revascularization of the SMA should be prioritized.[46,47] Last, if proceeding with intervention of the CA, extrinsic compression from conditions such as median arcuate ligament syndrome must be considered.

Access and Intervention

Before intervention, review of contrasted axial imaging is essential to obtaining procedural success, with both the CA and SMA often located between the level of T12 and L1. It is strongly recommended that experienced interventionalists and surgeons perform these procedures, given the high risk for complications such as AMI. Mesenteric interventions can be accomplished via brachial or femoral access with either a percutaneous or open approach. If proceeding with brachial artery access, open surgical exposure can reduce the risk of postoperative brachial sheath hematoma, nerve injury, and bleeding. Routine access with a Cook micropuncture kit (including a 21-gauge needle, 0.018 micropuncture wire, and 4-Fr micropuncture sheath) or 18-gauge needle and Bentson wire under ultrasound guidance is recommended at either the femoral or brachial artery. A diagnostic aortogram can be obtained if preoperative axial imaging is not available with 30-degree right anterior oblique (RAO), 30-degree left anterior oblique (LAO), and 90-degree lateral projections. Before sheath upsizing or cannulation of mesenteric vasculature, patients should be therapeutically heparinized (80–100 u/kg), unless there is an absolute contraindication. The goal activated clotting time (ACT) should be equal or greater than 250 seconds.

For mesenteric interventions, a 5-Fr to 7-Fr hydrophilic sheath measuring 70 to 90 cm is positioned either in the descending thoracic aorta (via brachial artery approach) or distal visceral abdominal aorta (via femoral artery approach). A 5-Fr multipurpose angiographic (MPA) catheter is most commonly used for selective catheterization from the brachial artery approach. Reversed or double-curved catheters such as the Simmons 1, SOS Omni, VS1, Cobra, and Mikelson devices are used for selective catheterization from the femoral artery approach. For technically difficult patient anatomy and in the treatment of mesenteric chronic total occlusions (CTOs), steerable introducer sheaths have been associated with high technical success and reduction in radiation dose during recanalization of the SMA.[48] A preintervention angiogram of the SMA or CA should be obtained to identify the location and characterize the quality of your target lesion. An 0.035-inch soft-angled Glidewire is used to cross the target lesion and subsequently exchanged for an 0.018-inch or 0.014-inch stiff guidewire/interventional wire. The distal end of the interventional wire should be positioned within the main trunk of the SMA to prevent perforation or dissection of smaller jejunal branches. The use of embolic protection devices (EPDs) can be considered for patients with occlusive, highly calcified, acutely thrombotic, or long (>30 mm) target lesions. A buddy wire system is required for deployment of an EPD, using both an 0.014-inch filter wire and 0.018/0.035-inch interventional wire for support and stent deployment. Even with the use of EPDs, distal embolization has been reported in 6% to 8% of patients undergoing mesenteric stenting.[49]

After crossing the selected lesion, predilation with a 3- to 5-mm low-profile plain angioplasty balloon (percutaneous transluminal angioplasty [PTA]) is used selectively before stent deployment. Balloon-expandable, covered stents have demonstrated superior patency rates compared with bare metal stents.[50–52] Stent sizing ranges from 5 to 8 mm based on preintervention angiography, although the use of intravascular ultrasound (IVUS) has also been anecdotally described in the literature.[53] Deployment of balloon-expandable, covered stents under fluoroscopic guidance is critical, with extension proximally 1 to 2 mm into the aortic lumen and distally 1 to 2 mm past the target lesion (Fig. 106.4). Postdeployment angioplasty can be used to flare the proximal portion of the stent at the mesenteric ostia and treat residual stenosis measuring greater than 50% of the arterial lumen. Postdeployment angiography should be completed to ensure patency of the CA or SMA and identify residual dissection, distal embolization, or mesenteric perforation. Suction thrombectomy devices can be used in the setting of distal embolization. However, conversion to open repair may be required if there is radiographic evidence and clinical concern for bowel ischemia or hemodynamically significant intraabdominal bleeding.

Open Surgical Revascularization

General Revascularization Principles

The role of open revascularization is reserved for younger patients, those without suitable anatomy for endovascular interventions, or patients with recurrent symptoms despite previous mesenteric angioplasty, stenting, and adjunctive therapies.[53] Revascularization strategies include antegrade mesenteric bypass from the distal

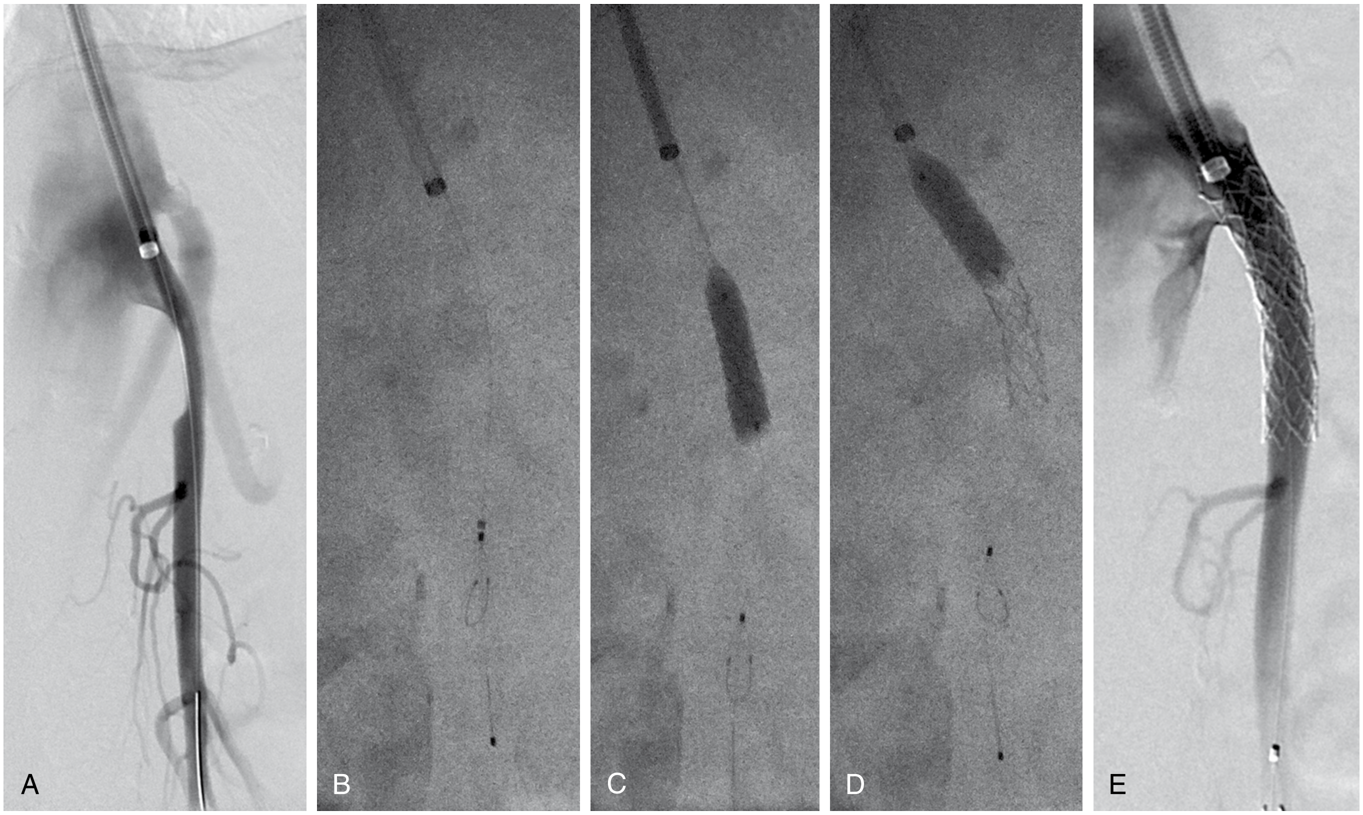

FIGURE 106.4 (A–E) Angioplasty and stenting of disease of the superior mesenteric artery (SMA) with deployment of balloon-expandable covered stent flared proximally into the aortic lumen. Completion angiography demonstrates patent stent within the SMA without dissection, residual stenosis, or distal embolization.

thoracic or supraceliac aorta, retrograde bypass from the infrarenal abdominal aorta or iliac arteries, ROMS, and transaortic mesenteric endarterectomy. In addition to routine preoperative risk stratification and medical optimization, other technical considerations include operative approach (transperitoneal vs. retroperitoneal), conduit type (prosthetic vs. vein graft), and quantity of target vessel reconstruction (single vs. multiple). A self-retaining retractor system is required for all open revascularizations and sterile preparation of bilateral lower extremities may be required if harvesting greater saphenous vein conduit.

Antegrade Mesenteric Bypass

For patients undergoing antegrade mesenteric bypass with inflow via the distal descending thoracic aorta or supraceliac abdominal aorta, a retroperitoneal or transperitoneal approach can be performed. Given the physiologic stress caused by supraceliac aortic cross-clamping, this type of revascularization is often reserved for younger patient populations. The antegrade approach has the benefit of reduced graft kinking. Additionally, the supraceliac aorta has notably less atherosclerotic disease burden.

The retroperitoneal approach to antegrade mesenteric bypass provides limited distal exposure of the SMA and CA, and should be reserved for patients with lesions at the vessel origin. The patient is flexed at a 60-degree angle in the left lateral decubitus position, with appropriate padding of both arms to prevent neural injury. A thoracoabdominal incision at the eighth rib interspace is performed. The transversalis fascia is divided and the retroperitoneal space is entered, ensuring not to violate Gerota's fascia. The left kidney is reflected down to allow for complete dissection of the SMA distal to the occlusion. Once the left renal artery has been identified, cephalad to the renal vein, overlying aortic retroperitoneal tissue can be divided in standard fashion. Proximally, the median arcuate ligament and diaphragmatic crura are divided to expose the supraceliac aorta. Small phrenic arteries may require ligation and division. Five to 10 cm of supraceliac aorta is required for safe cross-clamping. The SMA is then identified anteriorly, dissected, and isolated to the level of the middle colic artery using electrocautery, sharp dissection, and vessel loops. If possible, proximal jejunal branches should also be identified and isolated, ensuring not to injure these vessels with excessive traction. If performing revascularization of the CA, individual dissection and isolation of the splenic and common hepatic arteries is recommended. Patients are then systemically heparinized (60–80 u/kg) with a goal ACT greater than 250 seconds. The anesthesia team should be informed before aortic cross-clamping. Partial cross-clamping with a Satinsky clamp or total cross-clamping of the supraceliac aorta with two straight versus angled cross clamps (Cherry supraceliac, Fogarty hydragrip, and Wylie hypogastric clamp) is then performed for proximal control. A variety of conduits can be used in this type of revascularization, including but not limited to Dacron, PTFE, autologous vein, and CryoVein. Revascularization of both the CA and SMA requires a 12 × 6-cm or 14 × 7-cm bifurcated Dacron graft, whereas primary revascularization of the SMA does not require a bifurcated conduit. An arteriotomy is made 7 to 10 cm above the CA and extended with Potts scissors. The proximal Dacron graft is appropriately beveled and then anastomosed to the supraceliac aorta in an end-to-side fashion using 3-0 versus 4-0 Prolene. The celiac anastomosis can be performed in an end-to-end fashion with the right limb of the bifurcated graft using 4-0 versus 5-0 Prolene (an alternative approach being an end-to-side anastomosis at the common hepatic artery). The left or lateral limb of the bifurcated graft is then anastomosed to the SMA, distal to the target lesion in an end-to-side fashion using 4-0 versus 5-0 Prolene. SMAs with extensive disease may require endarterectomy or stent removal in the setting of previous endovascular intervention. Following appropriate flushing techniques, the proximal and distal bypasses should be interrogated with Doppler or intraoperative DUS.

For patients undergoing a transperitoneal antegrade mesenteric bypass, the patient is positioned supine on the operating room table with a midline laparotomy performed in standard fashion from the xiphoid process to the pubis symphysis. A nasogastric tube (NGT) is placed to decompress the stomach and identify the esophagus intraoperatively. The peritoneal cavity is entered, and ligation of the triangular ligament is performed to mobilize the left lateral lobe of the liver. The liver is retracted, and the gastrohepatic ligament is carefully dissected, with left lateral retraction of the esophagus to prevent injury. The lesser omentum is incised, and the stomach is retracted inferiorly. The right diaphragmatic crus is divided to allow for exposure of the supraceliac aorta. Following meticulous dissection approximately 5 to 10 cm proximal to the CA, the supraceliac aorta is encircled with dampened umbilical tape. Attention is then turned to exposure of the SMA. The transverse colon is mobilized cephalad, the small bowel is eviscerated to the patient's right, and the ligament of Treitz is divided. The duodenum is medialized until a healthy portion of the SMA distal to the base of the mesentery is identified. The SMA and distal jejunal branches are carefully encircled with vessel loops. A retropancreatic tunnel can be created using blunt dissection along the anterior surface of the aorta if a distal SMA anastomosis is required. Patients are then systemically heparinized (60–80 u/kg) with a goal ACT greater than 250 seconds. The anesthesia team should again be informed before aortic cross-clamping. The supraceliac aorta is cross-clamped, and an arteriotomy is made with extension using Potts scissors. The proximal anastomosis is performed using 3-0 versus 4-0 Prolene with the surgeon's conduit of choice. The distal SMA anastomosis is then performed in an end-to-side fashion using 4-0 versus 5-0 Prolene. If performing a multivessel revascularization, a bifurcated graft and technique as described earlier is required. The bypass graft should be flushed and deaired. Both proximal and distal bypasses should be evaluated with Doppler or intraoperative DUS. The abdomen is copiously irrigated and closed in multiple layers after ensuring appropriate hemostasis.

Retrograde Mesenteric Bypass

When considering a retrograde mesenteric bypass, inflow target vessels include the distal abdominal aorta, right CIA, left CIA, or external iliac arteries (EIAs) in the setting of proximal calcific disease. The desired inflow target is the right CIA as it allows the bypass graft to lie within a C-shaped configuration proximally to the SMA (Fig. 106.5). On principle, aortic cross-clamping should be avoided when possible. A transperitoneal approach is commonly described, although retrograde revascularization can be performed via the retroperitoneal approach. Similar to antegrade revascularization, conduit options are highly dependent on surgeon preference and multivessel revascularization requires bifurcated conduits.

A midline laparotomy incision from the xiphoid process to the pubic symphysis is first performed, and the peritoneal cavity is entered in standard fashion. The infrarenal abdominal aorta is exposed by eviscerating the small bowel to the patient's right and the transverse colon cephalad. The retroperitoneum is incised to the right of midline to avoid the IMA. Retroperitoneal dissection

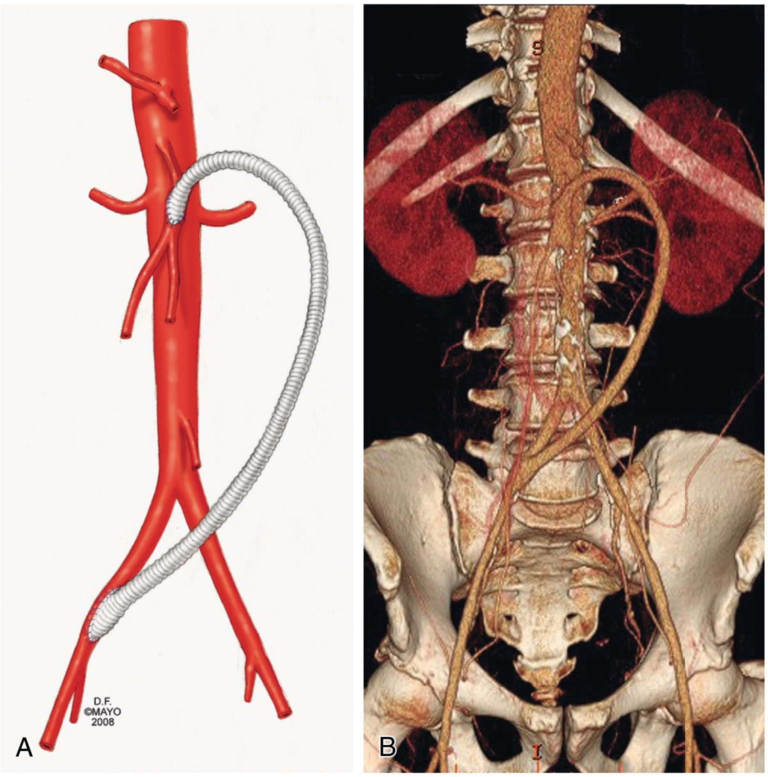

FIGURE 106.5 (A–B) Schematic representation and completion 3D CT angiography of retrograde mesenteric bypass from right common iliac artery to proximal superior mesenteric artery with C-shaped configuration to prevent graft kinking.

is carried down to the aortic bifurcation and then to the preferred iliac inflow target. The ureters are commonly retracted laterally, and careful dissection of the proximal CIA is required to avoid injury to the accompanying iliac veins. After isolating the inflow target circumferentially, attention is turned to dissection and isolation of the proximal SMA and distal jejunal branches starting at the root of the mesentery, as described earlier. After systemic heparinization with a goal ACT of greater than 250 seconds, the CIA is clamped. A longitudinal arteriotomy is performed and extended with Potts scissors. The bypass graft or venous conduit is beveled appropriately, and an end-to-side anastomosis is performed with 4-0 or 5-0 Prolene. The graft is then tunneled laterally along the left paracolic gutter, above the duodenum, and anterior or posterior to the pancreas in a C-shaped configuration. The proximal SMA anastomosis is then performed in a similar end-to-side fashion with 4-0 or 5-0 Prolene. An end-to-end configuration can be performed in the setting of a proximal mesenteric occlusion, with ligation of arterial inflow. The graft should be flushed and deaired, ensuring hemostasis at both suture lines. The small bowel and colon are returned to anatomic position, and the abdomen is copiously irrigated and closed in layers.

Retrograde Open Mesenteric Stenting

ROMS was first described in 2004 and has been widely adopted in the treatment of AMI.[54,55] It is considered a revascularization alternative for CMI patients who are not candidates for antegrade or retrograde (aortomesenteric or iliomesenteric) bypass. ROMS uses both open surgical principles and endovascular technology for mesenteric revascularization. A midline laparotomy to expose the infracolic SMA is performed. The SMA distal to the pancreas and associated jejunal branches is dissected and isolated with vessel loops. After systemic heparinization, retrograde SMA access is established using a micropuncture set, which is then exchanged for an 0.035-inch guidewire system. A short 5- to 7-Fr sheath is placed and diagnostic mesenteric angiography is performed to identify the target lesion. The target lesion is crossed and treated with subsequent angioplasty and balloon-expandable, covered stenting as described previously (Fig. 106.6). Completion angiography is performed, and the sheath is flushed copiously before removal. The SMA arteriotomy is closed primarily or via patch angioplasty. The abdomen is then irrigated and closed in multiple layers after ensuring appropriate hemostasis.

Postoperative Complications, Surveillance, and Outcomes

Postoperative Complications

Although mesenteric angioplasty and stenting is considered minimally invasive, the risk of complications is not insignificant. Intraoperative and postoperative complications include but are not limited to access site hematoma, dissection, and median nerve injury (with brachial artery access); residual stenosis, stent dislodgement, fracture and compression; mesenteric dissection, embolization or occlusion; and branch perforation, mesenteric hematoma, and/or AMI. Patients undergoing mesenteric intervention are also at high risk for major adverse cardiac events (MACE), pulmonary complications, and gastrointestinal bleeding.[56] All patients who undergo mesenteric stenting should be treated with an antiplatelet agent and cholesterol-lowing

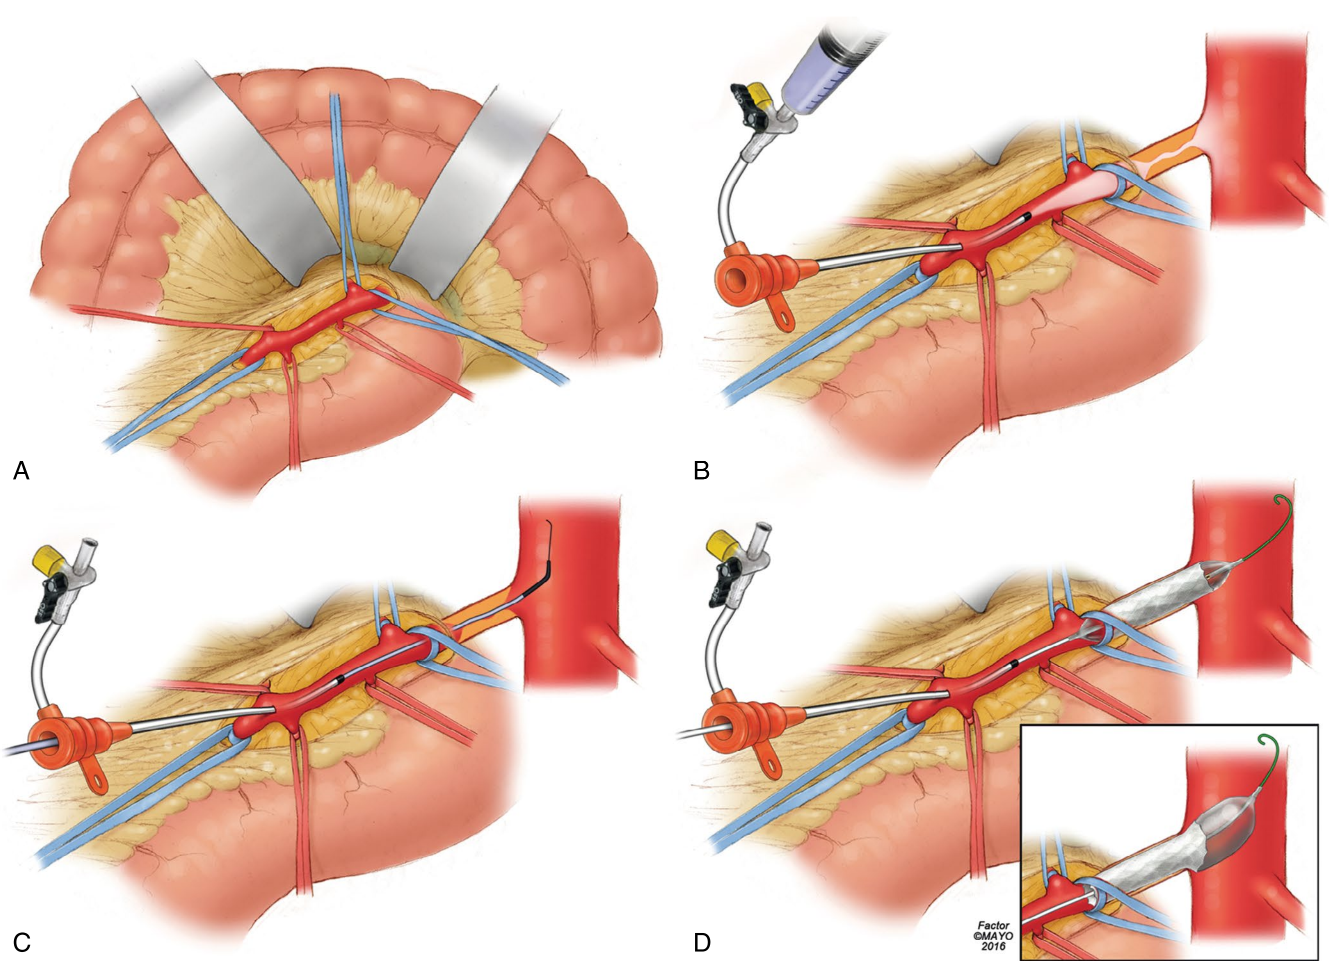

FIGURE 106.6 Technical steps for retrograde open mesenteric stenting. (A) Isolation of the infracolic superior mesenteric artery (SMA) with proximal jejunal branches. (B) Retrograde arterial access of SMA with placement of therapeutic sheath and catheter. (C) Crossing of target lesion. medication postoperatively. There are currently no randomized controlled trials (RCTs) or consensus guidelines regarding single versus dual-antiplatelet therapy (DAPT) after mesenteric intervention. However, DAPT is widely used for 6 to 12 weeks after stenting with the goal of preventing in-stent thrombosis. Individual patient factors must be considered given the increased bleeding risk for patients treated with DAPT.[57]

Open mesenteric revascularization is associated with longer length of stay and higher rates of overall pulmonary, cardiovascular, gastrointestinal, and cardiac complications given the invasive nature of this type of intervention.[58–60] Prolonged ileus occurs in approximately 10% of patients and can require perioperative parenteral nutritional support. Early graft thrombosis is uncommon, associated with technical defect, poor outflow, or hypercoagulable state.[60] Similar to patients undergoing endovascular revascularization, postoperative antiplatelet therapy and cholesterol-lowing medication are recommended, although consensus regarding single versus DAPT therapy remains unresolved.

Surveillance

With regard to postoperative surveillance, the SVS recommends a close, interval follow-up schedule with repeat imaging (CTA vs. mesenteric DUS) within 1 month of the index intervention, biannually for the first 2 years, and then annually thereafter. For patients with evidence of restenosis as detected by DUS examination, CTA or catheter-based arteriograms are recommended for confirmatory testing. For patients with recurrent symptoms due to de novo lesions or recurrent stenosis, an endovascular-first approach is recommended as the initial option, with open revascularization reserved for lesions not amenable to endovascular intervention.[39]

Restenosis, Symptom Recurrence, and Mortality

Single-center retrospective data have demonstrated similarly high rates of symptom relief for both open and endovascular revascularization, ranging from 80% to over 90% at 24 to 36 months. Although open revascularization is associated with longer length of stay and higher rates of perioperative complications, endovascular therapies are associated with increased prevalence of restenosis and reintervention. Nearly one-quarter of this patient cohort required reintervention for primary- or secondary-assisted patency of mesenteric interventions. Last, with regard to long-term mortality, modern series have demonstrated no statistically significant differences in 2- to 3-year survival between open and endovascular revascularization.[61,62]

MESENTERIC VENOUS THROMBOSIS

Epidemiology

MVT is a disorder of blood coagulation that impairs venous return of the small and large intestine. Primary MVT occurs without an underlying trigger, and it is considered idiopathic and spontaneous. Secondary MVT occurs when patients carry a predisposing pathology or clinic condition, as discussed later. Although MVT is considered a rare clinical entity, it accounts for 5% to 15% of all mesenteric ischemic events and can be life-threatening in the setting of subsequent bowel infarction.[63]

Pathophysiology

Mesenteric venous drainage includes the superior mesenteric vein, which drains the ileocolic, middle colic, and right colic veins. The SMV joins the SV to form the portal vein (PV). The inferior mesenteric vein (IMV) drains the left colon and connects directly with the SV. The left gastric vein receives venous return from the distal esophagus and lesser curvature of the stomach and drains directly into the PV. MVT most commonly affects the SMV, whereas involvement of the IMV is rare (<5%–10% of cases).

Secondary MVT accounts for greater than 90% of most cases. The three categories of secondary MVT include *direct injury* (abdominal trauma, postsurgical insult, intraabdominal inflammatory states (i.e., pancreatitis and inflammatory bowel disease), *local venous congestion or stasis* (portal hypertension/liver cirrhosis, congestive heart failure, hypersplenism, obesity, and intraabdominal compartment syndrome), and *thrombophilia* (protein C/protein S deficiency, antithrombin III deficiency, active protein C resistance, JAK2 V617 gene mutation, neoplasms, oral contraceptive use, polycythemia vera, essential thrombocytosis, heparin-induced thrombocytopenia, lupus anticoagulant-antiphospholipid syndrome, cytomegalovirus [CMV] infection).[64,65]

It is estimated that specific hypercoagulable states are identified in 60% to 70% of patients with MVT and are considered a predictor of bowel ischemia.[66] The degree of bowel ischemia is dependent on the magnitude of venous thrombosis within the splanchnic circulation. Propagation of mesenteric thrombosis into major venous circulation, without adequate collateral drainage, will result in bowel congestion and edema followed by transmural intestinal infarction (Fig. 106.7). Acute MVT more commonly affects the ileum and jejunum, with relative sparing of the duodenum and colon compared with AMI.[66]

Clinical Presentation

Patients with MVT present with acute, subacute, and chronic symptomatology. Patients with acute MVT present with vague abdominal pain, out of proportion to physical examination, nausea, vomiting, and gastrointestinal bleeding in 15% to 50% of patients and hemodynamic instability in the setting of bowel ischemia/infarction.[66] Patients with subacute MVT demonstrate nonspecific symptoms for weeks to months without demonstrable physical examination findings. Chronic MVT is typically asymptomatic, often presenting with complications related to portal hypertension (ascites, variceal bleeding) and evidence of extensive collateral circulation on noninvasive imaging. Approximately 70% of patients present with acute versus subacute MVT.[67] Given these nonspecific symptoms, other causes of abdominal pain must be considered, including but not limited to peritonitis, intestinal obstruction, gastritis, peptic ulcer disease, inflammatory bowel disease, cholecystitis, appendicitis, AMI and intraabdominal malignancies.

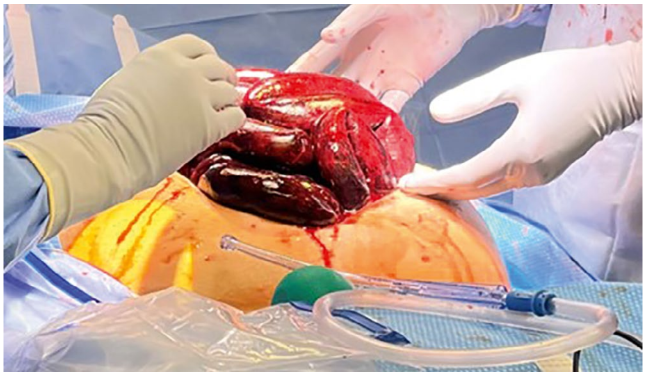

FIGURE 106.7 Bowel ischemia secondary to acute mesenteric venous thrombosis of a patient with intraabdominal trauma following motor vehicle collision. (From Acosta S, Bjorck M. Mesenteric venous thrombosis. In: Sidaway AN, Perier BA, eds. *Rutherford's Vascular Surgery and Endovascular Therapy*. 10th ed. Amsterdam: Elsevier; 2022:1779-1808.e2.)

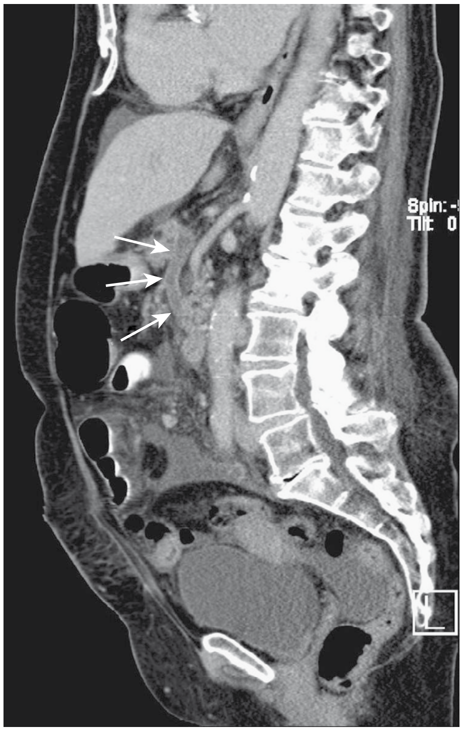

FIGURE 106.8 Sagittal view of superior mesenteric venous thrombosis on computed tomography *(arrows)*.

Routine laboratory assessment includes complete blood count, comprehensive metabolic panel, blood cultures, arterial lactate, inflammatory markers (erythrocyte sedimentation rate [ESR], CRP), amylase/lipase, thrombophilia screening, coagulation profile, and age-appropriate cancer screening, in addition to upper gastrointestinal endoscopy and cholangiography (for chronic MVT). Abdominal CT with and without IV contrast, including both arterial and portal venous phases, is considered the gold standard for diagnosis of MVT. Noninvasive imaging can demonstrate portal venous thrombosis, central venous thrombosis (first 5 cm of proximal SMV), peripheral venous thrombosis, ascites, small bowel dilation, bowel wall thickening, pneumatosis, portal venous gas, and pneumoperitoneum with associated bowel perforation (Fig. 106.8). Other imaging modalities include abdominal radiography, abdominal ultrasound, and MRA/magnetic resonance venography (MRV).

Management

The goal of treatment for MVT aims to prevent thrombus extension, intestinal infarction, and recurrent thrombosis.

Acute Mesenteric Venous Thrombosis

In the acute setting, IV unfractionated heparin should be administered immediately after diagnosis of MVT. For patients with acute or subacute presentation, management includes pain control, bowel rest, IV resuscitation and normalization of electrolyte imbalances, IV antibiotics to reduce incidence of bacterial translocation, and serial abdominal examinations. Gastrointestinal bleeding is rarely a contraindication to therapeutic heparinization, although blood product resuscitation may be required in select patient populations.[66] Patients with progressive peritonitis and impending transmural infarction require exploratory laparoscopy or laparotomy to assess bowel viability. If bowel resection is required, patients may undergo primary reanastomosis or require second-look operations within 24 to 48 hours of index exploration.

For patients without peritonitis but clinical worsening of abdominal pain despite systemic anticoagulation, endovascular therapies can be considered. Percutaneous transjugular intrahepatic portosystemic shunting (TIPS) with or without mechanical aspiration thrombectomy, percutaneous transhepatic mechanical thrombectomy, and percutaneous transhepatic thrombolysis are interventional techniques that allow for direct thrombus removal.[66] However, individual patient factors must be weighed against the increased bleeding risk associated with these invasive procedures. Therapeutic anticoagulation with warfarin therapy or direct oral anticoagulants should be continued for 6 months for patients with identifiable reversible conditions, and lifelong in patients with identified prothrombotic states or MVT of unknown etiology. Recurrent thrombosis within the mesenteric circulation can occur in up to 25% of patients, most commonly in the first 30 days. Patients maintained on systemic anticoagulation have reported recurrence rates as low as 3%. Presence of bowel resection, prothrombotic states, and use of oral contraceptive therapy are associated with recurrent disease. Average 30-day mortality rates vary widely (10%–30%) depending on the acuity and severity of initial presentation.[68]

Chronic Mesenteric Venous Thrombosis

For chronic MVT anticoagulation should be considered for patients with known prothrombotic states, although data remains limited on the long-term use of anticoagulation in this patient cohort. Patients with chronic MVT often require symptomatic or interventional management of esophageal and/or gastric varices, similar to patients with cirrhosis. TIPS is recommended for patients with refractory bleeding despite endoscopic or pharmacologic therapies, or in the setting of hemodynamic instability. Five-year survival rates for patients with chronic MVT range from 78% to 82%, with prognosis impacted by the nature and severity of underlying disease pathology (cirrhosis, malignancy, thrombophilia).[66]

CHAPTER 107

Dialysis Access

Yana Etkin and Karen Woo

OUTLINE

Background
Patient Selection for Hemodialysis versus Peritoneal Dialysis
Life Plan
Hemodialysis Access Selection
- Tunneled Dialysis Catheter
- Patient Evaluation for Arteriovenous Access Creation
- Arterial Inflow Evaluation and Treatment
- Central Venous Outflow Evaluation and Treatment
- Vein Assessment for Arteriovenous Fistula Creation
- Evaluation of Arteriovenous Graft Recipient Vessels

Arteriovenous Fistula Creation
Arteriovenous Graft Creation
Challenging Situations
Access for Peritoneal Dialysis
Postoperative Monitoring and Maturation of Arteriovenous Access
Long-Term Arteriovenous Access Complications
- Stenosis/Thrombosis
- Venous Hypertension
- Aneurysms/Pseudoaneurysms
- Infection
- Hemodialysis Access–Induced Digital Ischemia
- Ischemic Monomelic Neuropathy
- Tunneled Dialysis Catheter Complications
- Peritoneal Dialysis Catheter Complications

BACKGROUND

End-stage kidney disease (ESKD) requiring chronic kidney replacement affects nearly 800,000 patients in the United States with 126,000 new patients initiating kidney replacement annually.[1] In the United States, the overwhelming majority (84%) of patients with ESKD use hemodialysis (HD), 13% undergo peritoneal dialysis (PD), and 3% receive a kidney transplant annually.[1] HD can be delivered in-center or at home. In-center HD is typically delivered three times a week for 3 to 4 hours per session. Home HD can be administered 3 to 7 days a week with varying session duration. Home HD offers a more flexible schedule and increased patient autonomy, with fewer dietary restrictions and more liberal fluid intake. Longer treatment sessions may also reduce symptoms of fatigue and leg cramps while on HD. However, there is an increased need for assistance at home or family support with at-home dialysis. Reliable vascular access is a crucial component of HD.

PD is typically performed in the patient's home, as continuous ambulatory PD or automated PD. Continuous ambulatory PD is done by hand with multiple exchanges per day. Automated PD is done via a machine throughout the night and allows for the daytime hours to be free.

PATIENT SELECTION FOR HEMODIALYSIS VERSUS PERITONEAL DIALYSIS

When choosing PD versus HD, the initial decision typically occurs between the nephrologist and the patient. Patient preference should be the primary factor. There are a number of barriers for PD. Previous intraabdominal operation is the most common contraindication to PD catheter placement. Other barriers include obesity, ileostomy/colostomy, and prior transplant.[2] Additional factors that may make a patient a less ideal candidate for PD are advanced age, diabetes, heart failure, and hearing loss.[3] Measures that can ameliorate the barriers include parasternal PD catheter placement, use of low-volume dialysate, and use of vibration or light alarms for the hearing impaired.

If a patient chooses HD, the decision tree must consider whether the patient has viable options for arteriovenous (AV) access. For patients in whom viable vascular access options for HD have been exhausted, PD should be considered as an alternative. On the other hand, patients who cannot tolerate PD due to access complications, poor clearance, or inability to perform treatments on their own can be transitioned to HD.

LIFE-PLAN

The 2019 National Kidney Foundation Kidney Dialysis Outcomes Quality Initiative (KDOQI) guidelines focus on the ESKD Life-Plan.[4] This initiative calls for collaborative decision-making between the patient and their interdisciplinary kidney care team when formulating a plan for kidney replacement therapy. The Life-Plan includes determining the preferred modality of kidney replacement (HD vs. PD), setting (home vs. in-center), and access type based on the patient's medical comorbidities, anatomic limitations, and preferences. The primary principle of the Life-Plan is to create "the right access, for the right patient, at the right time, for the right reasons."[4]

HEMODIALYSIS ACCESS SELECTION

Vascular access options for HD include AV access (fistula or graft) and tunneled dialysis catheter (TDC). Patients who will receive HD should be referred to a vascular access surgeon at least 6 months before they are anticipated to start HD therapy.[4] Early referral allows adequate time for an arteriovenous fistula (AVF) to mature and possibly undergo any required maturation procedures or for a second AV access to be created if the initial access fails. The decision-making around placing a fistula or arteriovenous graft (AVG) is evolving. Historically, an AVF was considered to be superior to AVG in nearly all circumstances. However, there is increasing evidence that AVF may not have superior patency and function compared with AVG in all patients. In particular, the elderly may be more appropriate for AVG as they may have lower rates of AVF maturation.[5] Patients with limited life expectancy may not receive the long-term benefits of an AVF. A number of demographic characteristics and comorbidities may also negatively affect AVF maturation and patency, including female sex, coronary artery disease, diabetes, and obesity.[6,7] For predialysis patients for whom the Life-Plan suggests AVG, the creation should be performed as close to the start of HD as possible because AVGs have a higher risk of infection and generally lower patency than AVFs. Patients already HD dependent have more urgent need for functional long-term vascular access and AVG may be preferred in select circumstances as it is associated with earlier catheter removal and fewer catheter days than AVF. The decision regarding AVG versus AVF must be made on an individualized basis taking into account demographics, comorbidities, patient and family preferences, and the patient's Life-Plan.[4]

Tunneled Dialysis Catheter

Patients who choose to undergo HD and do not have a functioning AV access before initiation of dialysis require placement of a TDC. The catheter tip can be positioned in the superior vena cava via the internal jugular or subclavian vein or the inferior vena cava via the femoral veins. The catheter insertion should be performed under fluoroscopic guidance and vein access should be obtained with an ultrasound. Chest wall catheters are preferred because they are associated with less risk of infection compared with the lower extremity catheters. The right internal jugular vein is the preferred access because it provides a straighter path to the superior vena cava and is prone to less kinking/thrombosis. Similarly, the right femoral vein is a preferred access over the left side as the left iliac vein can sometimes be compressed by the right iliac artery. Subclavian vein catheters should be used only if bilateral internal jugular veins are occluded because catheter placement in the subclavian vein can lead to subclavian vein stenosis and subsequently compromise function of ipsilateral AV access. In the majority of patients, TDC should be considered a temporary access while a functioning AV access is being established. One advantage of TDC is that it can be used immediately after placement, but it is associated with significant longer-term complications, including infection, catheter dysfunction, and central venous stenosis, and should be reserved as a long-term access option for only a minority of patients.[4] Patients with short life expectancy (less than 9 months) may not be good candidates for AV access and chronic TDC should be considered. Patients with chronic hypotension and/or depressed cardiac output are also poor candidates for an AV access due to low patency rates. Finally, some patients find frequent cannulation and possible infiltration events to be unacceptably painful and strongly prefer TDC, a choice that should be respected by the kidney care team.

Patient Evaluation for Arteriovenous Access Creation

When counseling a patient regarding vascular access type, the surgeon is subject to multiple considerations, including patient anatomy, physiology, need to minimize catheter dwell time, and patient preference. Before creation of an AV access, a thorough history should be obtained, and physical examination performed on all patients. The evaluation should focus on previous AV access attempts, history of central venous catheters and devices, arterial inflow, superficial veins that can be used for an AVF, possible recipient outflow veins for an AVG, and central venous outflow. The nondominant arm is preferred for AV access placement. However, the dominant arm should be selected if the anatomic requirements for durable access are not present in the nondominant arm.

Arterial Inflow Evaluation and Treatment

All upper extremity pulses should be examined, and blood pressure measured in both arms. An upper extremity arterial duplex ultrasound (DUS) to assess brachial, radial, and ulnar arteries is advisable to confirm normal arterial inflow. The waveform in the intended inflow artery should be triphasic and the blood pressure should be equal in both arms. On ultrasound, the artery should have no more than a moderate degree of calcification. The brachial artery should be at least 3 mm in diameter and the radial and ulnar arteries should be at least 2 mm in diameter. An intact palmar arch and adequate ulnar inflow, as demonstrated by an Allen test, should be ensured before creating AV access using radial artery inflow. If neither arm has adequate arterial inflow at baseline, then the inflow of the nondominant arm should be treated, if possible.

Central Venous Outflow Evaluation and Treatment

A thorough history should include a detailed inventory of any central venous devices that the patient may have in place presently or in the past. Physical examination may reveal dilated chest wall veins and/or arm swelling suggestive of central venous stenosis/obstruction. If there is any suspicion of compromised venous outflow, a computed tomography venogram and/or catheter-based venogram should be performed. If neither arm has adequate venous outflow at baseline, the venous outflow of the optimal arm should be treated, if possible. The preferred treatment for central venous stenosis is endovascular balloon venoplasty. A stent may be required if significant recoil occurs. There is some evidence to suggest that the patency of stent grafts is superior to bare-metal stents.[8] In patients who have no other options for access and have a central occlusion on the ipsilateral side, open surgical options such as jugular venous turndown or bypass around the occlusion, if possible, may be considered.[9]

Vein Assessment for Arteriovenous Fistula Creation

The veins for the AVF creation need to be in a convenient location for puncture, reasonably straight, and not deeper than 6 mm under the skin. Ideally, the cephalic vein is used, due to its location and typically shallow course. If the basilic vein in the upper arm is used, transposition is required. The likelihood of functional maturity after AVF creation has been associated with increasing vein diameter. An absolute minimum vein diameter has not been established, but in general, veins greater than 2 mm in diameter may be considered for AVF creation.[10]

Evaluation of Arteriovenous Graft Recipient Vessels

A brachial or superficial vein in the antecubital fossa may be used for venous outflow of a forearm AVG if patent and of adequate diameter on DUS (Fig. 107.1D). Alternatively, the axillary vein can be used for upper arm AVG (see Fig. 107.1E–F).

ARTERIOVENOUS FISTULA CREATION

To determine the appropriate site for AVF creation, a distal-to-proximal and superficial veins first approach is recommended. Creation of initial AVF distally preserves more proximal vessels for future access sites. AVF using the cephalic vein is preferred over the basilic vein because using the cephalic vein is technically less challenging, does not require transposition, and may be easier to cannulate on HD.

Based on this approach, radiocephalic AVF should be considered first if adequate arterial inflow and venous outflow are available (see Fig. 107.1A). The forearm basilic AVF is another option for distal access and can be created using either the radial or ulnar artery. This is a particularly attractive option in younger patients with long life expectancies who may need numerous permanent vascular access sites over their lifespan.

When forearm AVF is not an option, upper arm cephalic fistula is typically considered next (see Fig. 107.1B). Using the proximal radial artery as in inflow is preferred over the brachial artery as it is associated with lower rates of access-related hand ischemia. If cephalic vein is not suitable, upper arm brachial artery to basilic vein AVF is another option (see Fig. 107.1C). It can be created in a single-stage or two-stage manner. The basilic vein is not anatomically located in an immediate subcutaneous position needed for access and it must be transposed to a more superficial and anterolateral position. In the single-stage procedure, the entire basilic vein is dissected out, transposed to a superficial position, and anastomosed to the brachial artery. In the two-stage procedure, the basilic vein is anastomosed to the brachial artery in the first operation, and at the second operation, the fistula is superficialized. The basilic vein can be superficialized by passing it through a superficial tunnel or placing the vein in a superficial pocket by creating a skin flap that is no more than 5 mm thick. Typically, 4 to 6 weeks elapse between the first and second stages to allow for maturation of the fistula. Some studies have demonstrated superior outcomes using the two-stage approach, whereas others showed no statistically significant differences in maturation rate and postoperative complications. One meta-analysis showed that brachiobasilic AVFs created via two-stage technique achieved higher maturation rates compared with the one-stage technique.[11] Another meta-analysis demonstrated no difference in 1-year primary and secondary patency rates between the one-stage and two-stage approach, despite the veins in the two-stage group being smaller in diameter. Three of the eight studies included in the meta-analysis preferentially reserved two-stage transpositions for patients with smaller veins. There was no difference in primary failure with one-stage transpositions (15%–45%) compared with two-stage transpositions

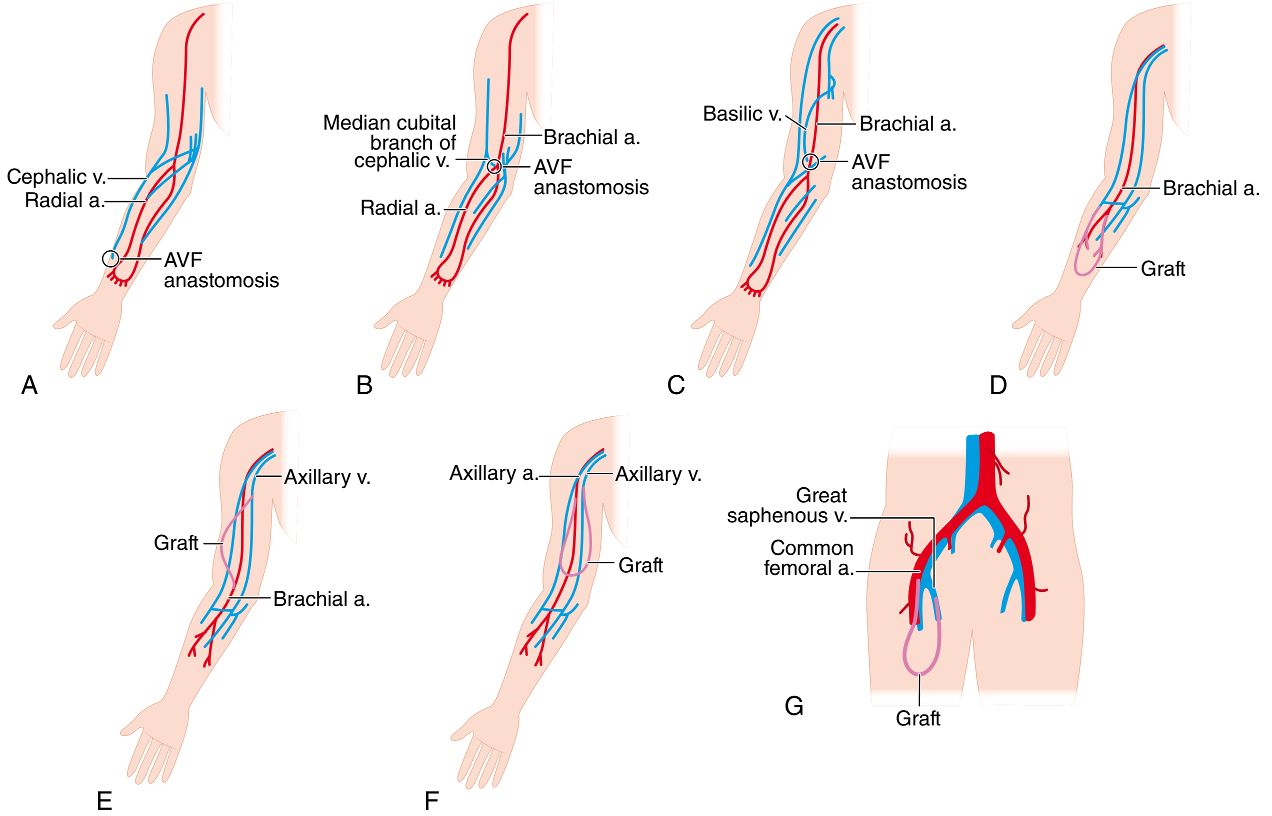

FIGURE 107.1 Arteriovenous fistulas *(AVFs)* and arteriovenous grafts *(AVGs)* configurations. (A) Radiocephalic AVF. (B) Brachiocephalic AVF. (C) Upper arm brachiobasilic AVF. (D) Forearm loop AVG (brachial artery to cephalic vein). (E) Upper arm straight AVG (brachial artery to axillary vein). (F) Upper arm loop AVG (axillary artery to axillary vein). (G) Thigh loop AVG (femoral artery to great saphenous vein. *a.,* Artery; *v.,* vein. (From Ultrasound Evaluation Before and after Hemodialysis Access. Radiology Key. [Pub date]. http://radiologykey.com/ultrasound-evaluation-before-and-after-hemodialysis-access/. [Accessed date].)

(10%–42%; $p = 0.46$).[12] This suggests that for smaller basilic veins the two-stage approach may be preferred.

As of 2020, there are two percutaneous AVF creation technologies available in the United States: Ellipsys (Avenu Medical, San Juan Capistrano, CA) and WavelinQ (Bard Peripheral Vascular Inc, Tempe, AZ). Both technologies rely on a perforator vein that connects the deep and superficial venous systems in the antecubital fossa. In patients who are candidates for radiocephalic AVF, percutaneous fistula should not be a first choice because it creates an upper arm fistula and bypasses the distal first approach. The procedure is performed through one or two punctures, depending on the device, and the anastomosis is relatively distal in the antecubital fossa. As such, “side-by-side” cannulation at the antecubital fossa, with one needle in the median basilic vein and one needle in the median cephalic vein, is possible, as is two-needle cannulation in the median basilic vein. This geometry may enable patients to avoid basilic vein transposition.

Although early results are promising, secondary procedures are frequently necessary to obtain functional maturity.[13] Further studies will be required to define the role of percutaneous AVF versus surgical AVF more clearly.

ARTERIOVENOUS GRAFT CREATION

Several types of prosthetic grafts are available for AVG construction. However, none have been shown to have superior patency or lower complication rates. The most commonly used is the expanded polytetrafluoroethylene (ePTFE) graft. Other available materials are heparin-bonded ePTFE and multilayer early-access grafts. ePTFE grafts are available as a conventional single-diameter tube and tapered versions that include a 4- to 7-mm taper and a 6- to 8-mm taper. Randomized comparisons of tapered grafts compared with conventional grafts have not demonstrated differences in access-related hand ischemia or patency.[7] Heparin-bonded ePTFE has not been shown to improve patency over conventional ePTFE grafts.[14]

Standard grafts require 2 to 3 weeks of tissue ingrowth after placement before the graft can be cannulated to avoid access site extravasation. Early cannulation grafts can be accessed within 24 hours after creation and can be used to decrease catheter dwell time. The 12-month primary patency of all the early cannulation grafts ranges from 43% to 63% and the secondary patency ranges from 70% to 86%.[15] There is some evidence in the literature that early access grafts have inferior patency rates compared with standard grafts.[16]

The infection rate of upper extremity AVG has been reported to be anywhere from 3.5% to 19.7%.[7] Patients who are immunocompromised, those with a chronic infection, or those who have had vascular access infections in the past are at an increased risk of AVG infection and biologic rather than prosthetic conduit should be considered. A number of biologic grafts are available including bovine carotid artery, bovine ureter, bovine mesenteric vein, cryopreserved human vein, and cryopreserved human artery. Of the bovine conduits, the bovine carotid artery is the most commonly used. It allows for earlier cannulation and has been shown to have superior primary and assisted primary patency rates compared with PTFE grafts with lower rates of infection.[17]

CHALLENGING SITUATIONS

For patients in whom the previously mentioned access options are not possible, less commonly used options can be considered. The brachial artery to brachial vein AVF is a technically challenging operation. The brachial vein is thin-walled and deep with numerous tributaries that require careful dissection and ligation. The median nerve runs close to the vein and must be carefully preserved. The brachial-brachial AVF can be created in one stage or in two stages, in the same manner as the brachial-basilic AVF. Although brachial-brachial AVF maturation and patency rates are inferior to brachiocephalic and brachiobasilic AVFs, brachial-brachial AVF offers an autogenous alternative for patients who do not have adequate superficial veins and may be preferable to an AVG, especially in young patients where it is important to preserve future access options.

Cervical-based AVG can be created in patients with axillary vein occlusion and patent central veins, using ipsilateral internal jugular vein or subclavian vein for outflow (Fig. 107.2A). In patients without any available options for arm access, a chest wall AVG may be considered. It requires adequate axillary artery inflow and axillary vein or internal jugular vein outflow. The graft can be performed in a looped manner between the ipsilateral axillary artery (see Fig. 107.2B) and vein or in a “necklace” configuration between the axillary artery and the contralateral axillary vein (see Fig. 107.2C).

For patients with central venous stenosis/occlusion that cannot be successfully treated but can be crossed using endovascular techniques, the HD reliable outflow (HeRO) graft (Merit Medical, South Jordan, UT) is an option for upper extremity access. The HeRO is a composite of a prosthetic graft and a catheter that is completely subcutaneous. The graft is anastomosed to arterial inflow in the arm, typically the antecubital or upper arm brachial artery, tunneled subcutaneously, and connected to the central catheter at the deltopectoral groove. One-year primary patency rates are 22% to 48%, and secondary patency is about 60%, as reported by several studies.[18]

If no arm access is possible, thigh access can be considered. In evaluating a patient for a lower extremity access, screening for peripheral arterial disease is imperative. Placement of a thigh access in patients with significant peripheral arterial disease can result in ischemic steal, leading to limb-threatening ischemia, gangrene, and amputation. Inflow can be from the common femoral artery, profunda, or superficial femoral artery with outflow into the common femoral, femoral, or great saphenous vein (see Fig. 107.1G).

AVF in the thigh is preferentially constructed using the transposed femoral-popliteal vein, which is a technically demanding operation involving a complex dissection and, as such, is reserved for good-risk patients. Femoral vein AVFs have been associated with 66% to 93% primary patency at 1 year.[19] Thigh AVF using the saphenous vein is less technically demanding; however, results are not satisfactory because of the lack of dilation of the great saphenous vein over time.[19] Prosthetic thigh AVGs are associated with a higher rate of infection than are arm AVGs but significantly lower rates of infections when compared with TDCs.

If all options for conventional and complex HD access procedures have been exhausted, several “exotic” alternatives have been described, including axillofemoral AVGs (see Fig. 107.2D) and axillocaval and femorocaval AVGs (see Fig. 107.2E). In the absence of suitable venous outflow options for conventional access, an alternative approach is an arterioarterial prosthetic loop graft (see Fig. 107.2F).

ACCESS FOR PERITONEAL DIALYSIS

A PD catheter can be placed via open, laparoscopic, or percutaneous surgical approaches. There is about a 10% to 35% catheter malfunction rate reported when using the open technique and 2.8% to 13% catheter failures for the laparoscopic insertion technique.[7] Perceived benefits of the laparoscopic approach would be better visualization during the procedure and increased patient satisfaction. The laparoscopic approach also allows for tacking the omentum up to the abdominal wall should it reach into the pelvis. Based on a recent meta-analysis comparing percutaneous versus surgical placement, significantly lower rates of exit-site infections and peritonitis were observed in the percutaneous group at 30 days without any difference in mechanical complications.[20]

POSTOPERATIVE MONITORING AND MATURATION OF ARTERIOVENOUS ACCESS

After an AV access is created, the first evaluation should occur approximately 2 weeks after the procedure to assess the incision site and to identify any potential postoperative complications including thrombosis, pain, infection, numbness, swelling, and distal ischemia. The early access graft materials can be used within 24 hours or creation and other graft materials can be accessed within 2 to 4 weeks, once the incisions have healed and perigraft edema has resolved. AVFs need follow-up to evaluate for maturation and need for potential interventions to assist maturation. The first assessment for maturity should be done 4 to 6 weeks postoperatively. A thorough physical examination is the first step, which if done properly can provide a very accurate prediction of an AVF's readiness for use and detect major causes of AVF failure. The entire tract of the AVF should be palpated and a thrill should be felt in the venous outflow portion of a mature AVF. Absence of a thrill can suggest inflow or anastomotic stenosis, whereas pulsatile outflow without a thrill indicates an outflow stenosis. The AVF can be auscultated using a stethoscope, and a continuous systolic and diastolic low-pitch bruit should be heard in a mature AVF. Both arms, chest, and face should be examined looking for any

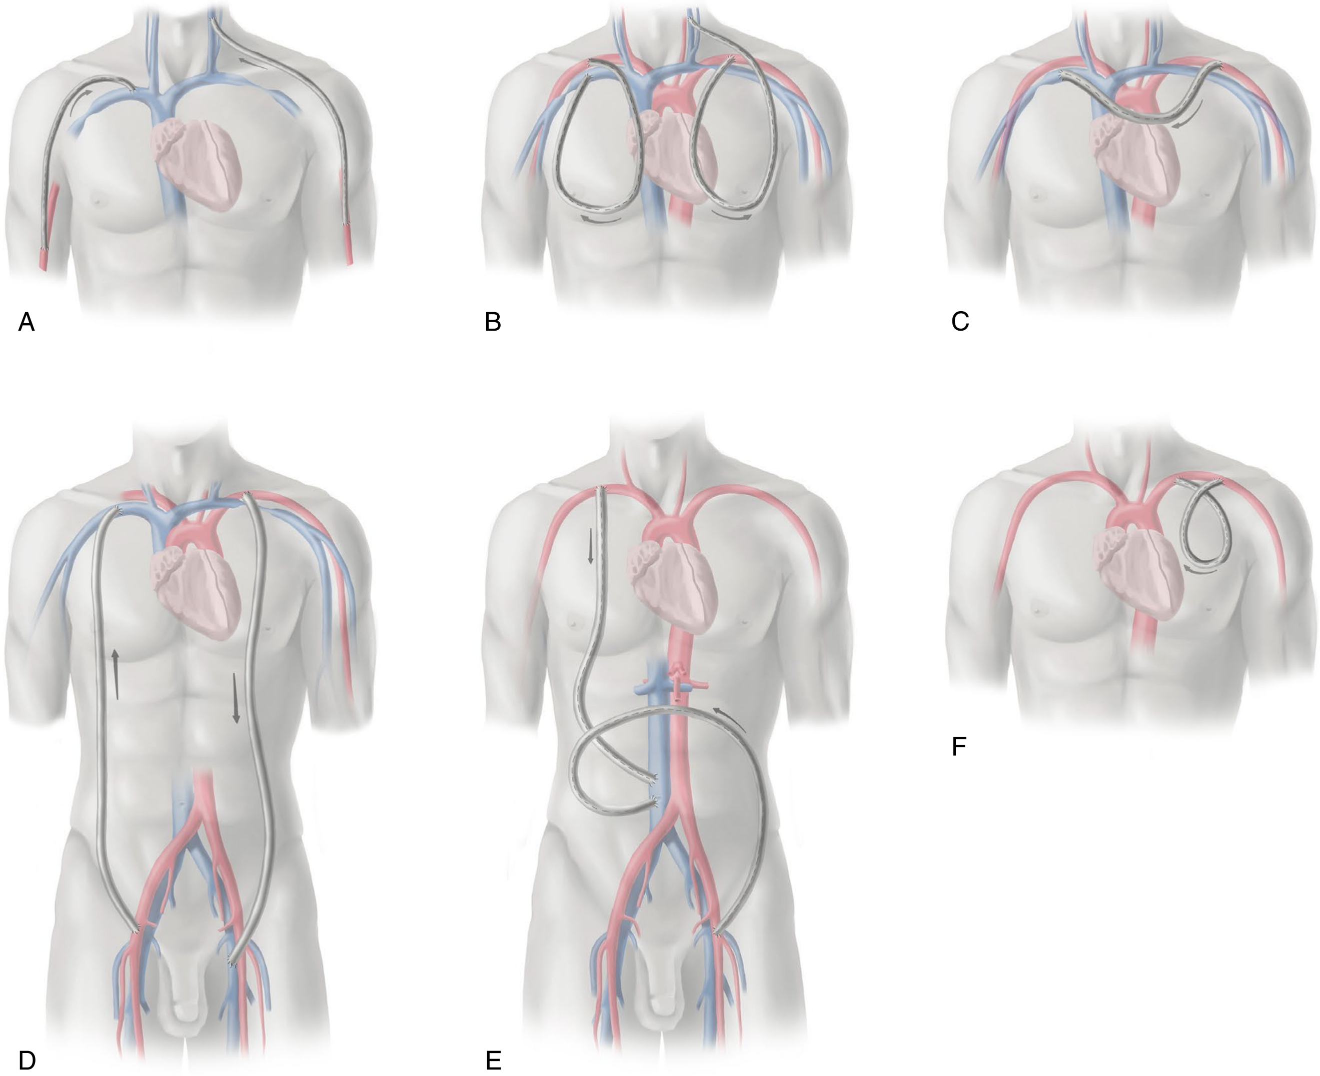

FIGURE 107.2 (A) Cervical-based arteriovenous grafts (AVGs) (brachial artery to subclavian vein or internal jugular vein). (B) Chest wall loop AVGs (axillary artery to ipsilateral axillary vein or internal jugular vein). (C) Chest wall "necklace" AVG (axillary artery to contralateral axillary vein). (D) Axillofemoral AVG (axillary artery to femoral vein or femoral artery to axillary vein). (E) Axillary artery to inferior vena cava AVG or femoral vein to inferior vena cava AVG. (F) Arterioarterial prosthetic loop graft. (From Schmidli J, Widmer MK, Basile C, et al. Editor's Choice - Vascular Access: 2018 Clinical Practice Guidelines of the European Society for Vascular Surgery [ESVS]. *Eur J Vasc Endovasc Surg*. 2018;55[6]:757-818.)

swelling in the ipsilateral or contralateral chest and arm as a sign of central venous stenosis/occlusion. The fingertips should be carefully inspected for any signs of poor perfusion such as pallor, cyanosis, or delayed capillary refill, which suggests possible HD access–induced distal ischemia (HAIDI). If physical examination is equivocal, ultrasound can be a useful adjunct in the evaluation of AVF maturation. The most important parameters assessed by DUS to predict AVF maturation include vein diameter, volume flow, depth, and presence of stenosis in the vein and/or at the anastomosis as well at the presence of competing branches. The current KDOQI guidelines suggest that a 4-week maturity assessment of a vein diameter should show at least 4 to 5 mm with a minimum volume flow of 400 to 500 mL/min, although the studies from which these recommendations are derived are largely underpowered and retrospective in nature.[4] In a recent study looking specifically at the role of DUS in AVF maturation assessment, the parameters most indicative of AVF maturation were vein diameter of 6 mm or more, absence of stenosis in the vein, absence of stealing branches, and a volume flow of more than 675 mL/min.[21]

KDOQI guidelines do not recommend routine surgical or endovascular intervention for postoperative maturation; instead, the decision to intervene should be made on a case-by-case basis.[4] In general, intervention is recommended by 6 to 8 weeks. Surgical and endovascular techniques such as revision and balloon-assisted maturation have shown promising results in assisting AVF maturation. Balloon-assisted maturation uses balloon angioplasty of long venous segments with the aim to expedite and optimize the maturation process. Coil embolization or ligation of competing branches can also be performed in tandem with the balloon angioplasty to facilitate flow increment across the preferred outflow tract. Balloon-assisted maturation can also be used to selectively reroute flow to the most optimal outflow tract for maturation with highest probability of reliable usage.

The most common surgical interventions to facilitate AVF maturation are proximal neoanastomosis and accessory vein ligation. Proximal neoanastomosis involves the creation of a new end-to-side anastomosis proximal to the stenotic region with the distal end ligated. Accessory vein ligation involves surgical ligation of accessory veins or stealing branches. By eliminating the stealing branches, the flow across the main outflow vein is increased thereby improving the rate of AVF maturation.

LONG-TERM ARTERIOVENOUS ACCESS COMPLICATIONS

Stenosis/Thrombosis

AV access complications are frequent and often lead to hospital admissions. Stenosis is the most common complication after AV access creation that can cause access dysfunction, inadequate HD clearance and thrombosis.[4] For AVFs, vein stenosis at the canulation sites and in the perianastomotic area are common causes of access malfunction. Stenosis at the venous anastomosis is associated with thrombosis in 80% of AVGs.[4] Currently, the majority of AV access stenoses/thromboses can be treated with endovascular techniques including percutaneous thrombectomy, balloon angioplasty of stenotic areas, and in some cases stenting. Open thrombectomy and/or access revision are reserved for patients in whom percutaneous techniques were not successful.

Venous Hypertension

Swelling of the entire extremity after AV access creation is indicative of central venous stenosis or occlusion, which is frequently related to previous central venous catheters or devices. In general, swelling in the ipsilateral arm alone suggests a subclavian vein stenosis; swelling involving both ipsilateral arm and face suggests an innominate vein stenosis; and swelling in both arms and face indicates a possible superior vena cava stenosis. The presence of prominent veins across the chest is another sign of central venous stenosis. The treatment options include conservative management with arm elevation and compression, percutaneous angioplasty and stenting, and central venous reconstruction with a bypass of occluded vein or jugular turndown procedure. If a patient is not a good candidate for these interventions or repeated interventions have failed, AV access ligation should be considered.

Aneurysms/Pseudoaneurysms

Aneurysms of AV conduits is another common complication. Most AVF aneurysms are true aneurysms, whereas all the AVG aneurysms are pseudoaneurysms. These aneurysms can lead to functional impairment and access thrombosis, loss of skin integrity, bleeding, and rupture. Some patients may also have cosmetic concerns. The goals of treatment are centered around prevention and treatment of complications, prolonging access life while avoiding compromising future access options, and minimizing number of interventions. Observation is acceptable for most stable AVF aneurysms. The indications for interventions include pseudoaneurysms, bleeding, pain, infection, skin ulcerations, and large or multiple tortuous aneurysms. In some patients, cosmetic concerns may drive interventions as well. In patients who need interventions the outflow stenosis should be evaluated and treated first.

AVG pseudoaneurysms are due to weakness in the wall of the graft from repeated needle cannulations, which heal with fibrous tissue replacing segments of the prosthesis with collagen, which expands under pressure. Small, stable puncture site pseudoaneurysms may be observed while expanding, and infected or anastomotic pseudoaneurysms require treatment. Treatment options include percutaneous covered stent placement or open surgical repair with segmental replacement of the graft. AVG pseudoaneurysms can be effectively excluded with covered stents. However, true aneurysms of AVF can continue to dilate after placement of covered stents, making covered stents ineffective. Surgical AVF salvage options include aneurysmorrhaphy, excision of redundancy, and primary anastomosis or AVG interposition. Selective ligation and excision might be appropriate in patients with functional renal transplant.

Infection

Infection is the second leading cause of mortality in the ESKD patient population, accounting for 8% of all deaths.[22] The incidence of infections is higher in AVG than AVF. AVG infections have been reported to occur in up to 1.6% to 35% of patients, with an overall incidence of positive blood cultures of 0.31/1000 days.[4] The median rate of AVF infections is about 0.11/1000 days and positive blood culture rate of 0.08/1000 days.[4] Patients commonly present with pain, erythema, induration, and drainage around the access sites. They may also have manifestations of a systemic infection such as fever, hypotension, bacteremia, and sepsis. Skin organisms *Staphylococcus aureus* and *Staphylococcus epidermidis* account for 70% to 90% of AV access infections.[4] Management includes broad-spectrum antibiotics and source control. Blood cultures should be obtained before the initiation of antibiotic therapy. Preservation of AV access might be possible if infection only involves the overlying skin and does not extend down to the access. In the majority of cases, access infections are treated surgically, which includes partial or complete access excision or attempted access salvage with in situ or extraanatomic reconstruction. The choice of the operation depends on the extent of the infection, the offending organism, the type of access, the location of the infection, the presence of systemic signs, the presence of bleeding, and, importantly, future dialysis access options.

Hemodialysis Access–Induced Distal Ischemia

The incidence of hand ischemia in patients with HD access ranges from under 1% in forearm fistulas to as high as 8% in antecubital based fistulas.[23] The onset of ischemia after AVG placement commonly occurs in the acute phase (within 30 days postoperatively) or subacute phase within a year of access placement. Ischemia after AVF placement is more likely to occur after the access has been used for several years. Society for Vascular Surgery guidelines classify HAIDI into four grades, ranging from no symptoms in grade 0 ischemia to ischemic rest pain and tissue loss in grade 3 ischemia. Several risk factors have been identified including advanced age, female sex, diabetes, peripheral vascular disease, large outflow conduits, multiple prior access procedures, prior episode of steal, and using brachial artery as an inflow.[4]

There are a number of strategies to prevent arterial steal that should be considered during HD access planning and creation. Preoperative testing to identify and potentially treat proximal arterial lesions should be done. When creating antecubital-based fistulas, ligation of the deep perforating branch is recommended to perform selective venous arterialization of either the cephalic or basilic vein instead of arterializing both. It is beneficial to minimize the use of brachial artery as inflow and create radiocephalic fistula in the distal forearm when feasible or use proximal radial artery for inflow when creating upper arm fistulas. The deep perforating branch can be used for anastomosis in this location or should be ligated. Currently, there is not enough evidence to support the use of taped grafts to reduce the incidence of hand ischemia.

The workup of HAIDI should include photoplethysmography with and without fistula compression as well as fistula DUS to measure volume flow and evaluate for the presence of flow reversal in the artery distal to the anastomosis. The management of HAIDI depends on the amount of flow in the fistula. High-flow fistulas (>1 L of flow) can be treated with banding or revision using distal inflow, whereas low/normal flow access can be treated with distal revascularization interval ligation (DRIL) or proximalization of arterial inflow (PAI). Radial artery ligation distal to the AV anastomosis can be considered for any radiocephalic fistulas irrespective of flow as long as the palmar arch is intact. In cases of severe ischemia, especially if digital gangrene is present, ligation of HD access should be strongly considered.

Banding is the least invasive procedure and should be considered first for high-flow access. There are several banding techniques described in the literature with various adjunctive techniques that allow for measurements of digital perfusion during the procedure.[24]

Although banding is the least invasive technique, it is associated with the highest rate of failure to manage HAIDI (33%) and well as the highest rate of access thrombosis (11%).[25] Revision using distal inflow is performed by ligating the fistula just distal to the anastomosis and reestablishing inflow from more distal on the arm, preferably the ulnar or radial artery. DRIL reliably restores antegrade flow, eliminates a potential physiologic pathway for ischemia, and maintains continuous dialysis access, which is especially important in patients with difficult access. However, it requires ligation of antegrade native arterial flow to the hand. Although DRIL might be the most effective procedure, there is a reluctance to ligate normal arteries supplying the distal arm, which led to the development of alternative treatment options including PAI. This technique does not sacrifice natural arterial continuity. Proximal arterial anastomosis increases flow to the forearm by increasing pressure at the split point between the distal circulation and the dialysis access. It also initiates collateral flow at a higher point in the arm, which is advantageous to prevent or treat ischemic symptoms in the hand. A study that evaluated the effects of six HD access modifications on forearm flow showed that PAI approached DRIL in degree of improvement of forearm flow and appeared to be as effective without sacrificing natural arterial continuity.[26]

Ischemic Monomelic Neuropathy

Ischemic monomelic neuropathy is uncommon and a potentially devastating complication of brachial-based AV access procedures. Diabetes and female sex are the primary risk factors. The onset of symptoms is usually within hours after the access creation and can lead to irreversible dysfunction of radial, median, and ulnar nerves producing claw hand deformity. The presentation can be similar to HAIDI except for the presence of palpable pulses distal to the access and absence of severe tissue ischemia in the affected extremity. Early diagnosis and intervention with access ligation is the only treatment that can potentially reverse the dysfunction. Recovery is unpredictable and even with appropriate management strategies and early intervention, patients may be left with a significant deficit.

Tunneled Dialysis Catheter Complications

TDC complications include catheter dysfunction, infection, migration, and central venous thrombosis. TDC dysfunction often leads to inadequate dialysis, which can be associated with increased morbidity and mortality. The incidence of TDC dysfunction is reported to be as high as 7% of HD sessions.[4] TDC dysfunction often requires medical, endovascular, or surgical intervention and is performed in 20% to 40% of patients dialyzing via a TDC.[4] The initial management of TDC dysfunction involves bedside maneuvers such as positioning the patient in Trendelenburg position or the use of rapid saline flushes to dislodge a possible thrombus. If these initial maneuvers are unsuccessful, administration of a thrombolytic agent into each port can be tried next. If TDC dysfunction persists, catheter exchange or removal followed by replacement at a different site should be considered.

Patients dialyzing with a TDC are at increased risk of catheter-related infections and have increased morbidity, mortality, and healthcare costs. The incidence of the catheter-related infections are 1.1 to 5.5 episodes per 1000 catheter days.[4] TDC-related infections include exit-site infections, infections of the tunnel track, and bacteremia. Bacteremia is the most significant complication because it has the potential for hematogenous spread of the infection resulting in endocarditis, osteomyelitis, septic arthritis, epidural abscess, and life-threatening sepsis.[27] The common clinical features of TDC infection include fever or chills, hemodynamic instability, hypothermia, nausea and vomiting, and generalized malaise. If drainage is present from the exit site, cultures should be obtained before initiation of antibiotics. If there are signs or symptoms of systemic infection, peripheral blood cultures and cultures from the catheter should also be obtained. Broad-spectrum empiric antibiotic should be administered and modified based on the final cultures. Depending on the severity of symptoms, TDC can be removed and exchanged over a guidewire at the same site or a new TDC can be placed at a new site.

Peritoneal Dialysis Catheter Complications

PD catheter complications can be characterized into early postoperative complications and mechanical and infectious complications. The most serious perioperative complications are bowel or bladder perforation as well as hemorrhage. Visceral injury typically occurs during entry into the abdominal cavity or during advancement of the catheter into the pelvis. If bowel perforation is considered, it is crucial to recognize and confirm the diagnosis immediately. This can be done via visualization of bowel lumen, return of bowel contents from the dialysate effluent, or emanation of foul-smelling gas.[28] A through-and-through bowel perforation may temporarily mask some of these manifestations. If undetected, manifestations postoperatively include severe watery diarrhea, abdominal pain with hypotension, rigid abdomen, and peritonitis. Most microperforations can be managed by keeping the patient on nothing by mouth restrictions, giving prophylactic antibiotics, and close observation.

Bladder perforation can present with an increase in urine volume, hematuria, or bladder distention immediately after instillation of dialysis fluid. Importantly, this complication can go unnoticed as some of the holes of the PD catheter may remain outside the bladder; therefore, other diagnostic tools can be used to confirm the diagnosis including postoperative cystoscopy, cystogram, and other imaging.[28] Emptying the bladder and inserting a Foley catheter before PD catheter insertion are important preventive steps.

Hemorrhage of the inferior epigastric vessels may require ligation if noted intraoperatively or angiographic embolization if discovered postoperatively. On the other hand, intraabdominal trauma may result in mild bleeding that manifests as blood-stained effluent and is usually self-limiting. Bleeding at the exit site may also occur and is usually controlled with manual pressure, suture placement, injection with epinephrine, and frequent dressing changes.

Mechanical complications that occur after PD catheter placement are characterized as flow dysfunction or pericatheter leakage. Flow dysfunction can be due to extrinsic compression of the catheter tip, internal luminal obstruction, poor positioning and/or migration, and tissue attachment and entrapment.[28] Flow dysfunction mainly manifests as drain pain that is encountered upon draining the dialysate. This pain typically results from incomplete evacuation of dialysate fluid and typically occurs when the PD catheter is placed too deep in the pelvis. In most cases, catheter replacement is required. Peritoneal leakage complications can also occur with a reported frequency as high as 12.8%.[28] These leakages can broadly be categorized into pericatheter leaks, abdominal wall hernias, and pleuroperitoneal connection or fistula development. These complications can occur early or late after catheter placement.

Catheter-related infections are the most common reason for switching from PD to HD.[28] Infectious complications can be classified into exit-site infections, superficial cuff extrusion, tunnel infections, and peritonitis. Management of exit-site infections include obtaining culture and Gram stain of the drainage fluid and starting empiric antibiotics. For superficial cuff infection, catheter exchange can be avoided by removing the external cuff from the tubing and allowing the exit site to heal. Most tunnel infections are treated by removing the old catheter and inserting a new one using a different site. Once peritonitis is suspected, peritoneal fluid cultures are obtained and antibiotic therapy is initiated. The decision to change the catheter is dependent on the response to antibiotic therapy. The infected PD catheter can be exchanged over a wire if the patient is responding to the antibiotics. The lack of improvement after 5 days of antibiotic therapy necessitates catheter removal.[28]

Al Shakarchi J, Inston N. Early cannulation grafts for haemodialysis: an updated systematic review. *J Vasc Access*. 2019;20:123-127.

A systematic review of randomized trials and observational studies for early cannulation arteriovenous grafts yielded 19 studies that met inclusion criteria between 2007 and 2017. Four types of commercially available grafts were included in the studies. All grafts were found to be safely cannulated within 72 hours of graft placement. The pooled patency rate at 12 months ranged from 43.3% to 63.7% for primary patency and 70.5% to 85.8% for secondary patency. Statistical comparison of the grafts was not performed due to the heterogeneity of the population and the relative low sample size for each graft type.

Eroglu E, Heimbürger O, Lindholm B. Peritoneal dialysis patient selection from a comorbidity perspective. *Semin Dial*. 2022;35:25-39.

This review discusses conditions that may be considered relative contraindications to peritoneal dialysis (PD) and suggests appropriate actions to overcome potential issues related to these conditions. In general, there are few conditions/comorbidities that are an absolute contraindication to PD. The review outlines evidence that PD can be conducted successfully in elderly patients, those with diabetes mellitus, obesity, polycystic kidney disease, and history of abdominal surgery. PD may be suitable also in patients with liver cirrhosis, renal allograft failure, and acute dialysis requirement and those with congestive heart failure. The review of fundamental changes in healthcare policies include economic incentives, changes in the organization of healthcare with infrastructural changes, support to providers and healthcare professionals working with PD, and educational efforts to improve awareness of the potentials of PD among patients and healthcare workers and to improve their skills and experience in PD.

Habib SG, Jano A, Ali AA, Phillips A, Pinter J, Yuo TH. Early clinical experience and comparison between percutaneous and surgical arteriovenous fistula. *J Vasc Surg*. 2023;78(3):766-773.

A retrospective comparison was performed of 51 patients with percutaneous arteriovenous fistula (pAVF) and 51 randomly selected contemporaneous patients with surgical arteriovenous fistula (sAVF). Overall, the rate of maturation was similar between pAVF (72%) and 29 sAVF (57%) ($p = 0.11$). When all maturation interventions were combined, pAVF and sAVF had a similar incidence of maturation interventions (75% vs. 53%; $p = 0.69$). When planned second-stage transposition procedures were excluded, pAVF had a higher incidence of maturation procedures (74% vs. 24%, $p < 0.001$).

Three randomized controlled trials comprising 126 patients (47 two-stage and 79 one-stage) were included in this systematic review and meta-analysis of brachiobasilic vein fistula (BBVF). Two-stage BBVF had a lower incidence of maturation failure compared with one-stage BBVF (6.4% vs. 20.3%, P = 0.02). There was no significant difference in functional secondary patency.

Lok CE, Huber TS, Lee T, et al. KDOQI Clinical Practice Guideline for Vascular Access: 2019 Update. *Am J Kidney Dis*. 2020;75:S1-S164.

The National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (KDOQI) Clinical Practice Guideline for Vascular Access has been a comprehensive, evidence-based document for the management of hemodialysis vascular access since 1996. The 2019 update includes new topics, with the end-stage kidney disease "Life Plan" and related concepts as a central tenet of the guidelines. Other topics covered are vascular access choice, new targets for arteriovenous access (fistulas and grafts) and central venous catheters, and management of specific complications.

Superficial Venous Thrombophlebitis

Conclusion

Please access Elsevier eBooks+ to view the videos for this chapter.

This chapter provides the reader with a thorough overview of the physiology and pathophysiology of the venous system. Pathognomonic features of superficial and deep venous disorders are described, with discussion of appropriate diagnostic modalities and therapeutic interventions.

ANATOMY

To determine whether a pathophysiologic process is present, knowledge of venous anatomy is essential. Venous drainage of the legs is the function of two parallel systems, the superficial and deep venous systems, in anatomic continuity through connecting veins called *perforating veins*. The nomenclature of the venous system of the lower limb was revised in 2002, and the most relevant changes are addressed here.[1] The revised nomenclature is delineated in Tables 108.1 and 108.2.

Superficial Venous System

The superficial veins of the lower extremity form a network that connects the superficial dorsal veins of the foot and deep plantar veins. The dorsal venous arch, into which empty the dorsal metatarsal veins, is continuous with the great saphenous vein (GSV) medially and the small saphenous vein (SSV) laterally (Fig. 108.1).

The GSV arises from dorsal veins of the foot. The GSV extends cephalad and travels over the medial aspect of the tibia and in parallel to the saphenous nerve. As the GSV ascends through the thigh, multiple accessory branches are demonstrated, and variability in the number and location of these branches is the norm. The GSV travels within its own fascia, called the *saphenous sheath* (Fig. 108.2). This structure is superior to the deep fascia of the leg. Although a classic feature, the GSV can be contained completely within the saphenous sheath or exit the fascia and reenter at another point in its course along the extremity. In some cases, patients exhibit an incomplete saphenous sheath, which makes identification of the GSV difficult. The GSV terminates into the saphenofemoral junction (SFJ), where it is joined by the confluence of the superficial circumflex iliac veins, the external pudendal veins, and the superficial epigastric veins. It then ascends in the superficial compartment and empties into the common femoral vein after entering the fossa ovalis (see Fig. 108.2). The SFJ is a complex anatomic entity composed of one or several external pudendal veins, the superficial epigastric vein, the superficial circumflex vein, and one or several accessory saphenous veins, whose course in the leg can be anterior and posterior to the GSV. At the SFJ and a few millimeters distal in the thigh, the terminal valve and the preterminal are located.

The SSV arises from the dorsal venous arch at the lateral aspect of the foot and ascends posterior to the lateral malleolus, rising cephalad in the midposterior calf. The SSV continues to ascend, penetrates the superficial fascia of the calf, and then terminates into the popliteal vein. However, this anatomy is extremely variable. Most commonly, the SSV terminates within a lateral branch of the thigh, bypassing the classic saphenopopliteal junction. The sural nerve lies parallel to the SSV. This relationship becomes

TABLE 108.1 Deep Vein Thrombosis (DVT): Acute Versus Chronic

	ACUTE DVT	CHRONIC DVT
Length of time symptoms present	<4 weeks	>4 weeks
Ultrasound findings	Noncompressibility of the vein; hypoechoic thrombus within lumen, venous distention, and complete absence of spectral or color Doppler signal within the vein lumen; no collaterals	Partial to full compressibility, echogenic thrombus, collaterals, Doppler flow present
Anticoagulation	Anticoagulation recommended for treatment	No anticoagulation indicated

more intimate at the distal calf. A common vein branch that is the thigh extension of the SSV, also known as the *vein of Giacomini,* connects the SSV with the GSV.

Deep Venous System

The plantar digital veins in the foot empty into a network of metatarsal veins that compose the deep plantar venous arch. This continues into the medial and lateral plantar veins, which then drain into the posterior tibial veins. The dorsalis pedis veins on the dorsum of the foot form the paired anterior tibial veins at the ankle.

The paired posterior tibial veins, adjacent to and flanking the posterior tibial artery, run under the fascia of the deep posterior compartment. These veins enter the soleus and join the popliteal vein after joining with the paired peroneal and anterior tibial veins. There are large venous sinuses within the soleus muscle—soleal sinuses—that empty into the posterior tibial and peroneal veins. Bilateral gastrocnemius veins empty into the popliteal vein distal to the point of entry of the SSV into the popliteal vein.

The popliteal vein enters a window in the adductor magnus, at which point it is termed the *femoral vein,* previously known as the *superficial femoral vein.* The femoral vein ascends and receives venous drainage from the profunda femoris vein, or deep femoral vein, and after this confluence, it is the common femoral vein. As the common femoral vein crosses the inguinal ligament, it becomes the external iliac vein.

Perforator Veins

Perforating veins connect the superficial venous system to the deep venous system by penetrating the fascial layers of the lower extremity. These perforators run in a perpendicular fashion to the axial veins previously described. Although the total number of perforator veins is variable, up to 100 have been documented. The perforators enter at various points in the leg—the foot, medial and lateral calf, and mid- and distal thigh (Fig. 108.3). Some have been named by the surgeons who first identified them: Crockett perforators, which connect the posterior arch and posterior tibial veins; Boyd perforators, which connect the great saphenous and gastrocnemius veins; and Hunterian and Dodd perforators, which connect the great saphenous and superficial femoral veins, although these names are rarely used in patient care. The perforator veins have an important function. Their valve system aids in preventing reflux from the deep to the superficial system, particularly during periods of standing and ambulation. Perforating veins are currently identified by measuring their distance from the heel.

Normal Venous Histology and Function

The venous wall is composed of three layers, the intima, media, and adventitia. Vein walls have less smooth muscle and elastin than their arterial counterparts. The venous intima has an endothelial cell layer resting on a basement membrane. The intima enfolds, forming bicuspid valves whose function is to ensure venous return to the heart. The media is composed of smooth muscle cells and elastin connective tissue. The adventitia of the venous wall contains adrenergic fibers, particularly in the cutaneous veins. Central sympathetic discharge and brainstem thermoregulatory centers can alter venous tone, as can other stimuli, such as temperature changes, pain, emotional stimuli, and volume changes.

The histologic features of veins vary, depending on the caliber of the veins. The venules, the smallest veins, range from 0.1 to 1 mm and contain mostly smooth muscle cells, whereas the larger extremity veins contain relatively few smooth muscle cells. These

larger-caliber veins have limited contractile capacity in comparison to the thicker-walled GSV. The venous valves prevent retrograde flow; it is their failure or valvular incompetence that leads to reflux and its associated symptoms. Venous valves are most prevalent in the distal lower extremity, whereas as one proceeds proximally, the number of valves decreases to the point that no valves are present in the superior vena cava and inferior vena cava (IVC).

Most of the capacitance of the vascular tree is in the venous system. Because veins do not have significant amounts of elastin, veins can withstand large volume shifts with comparatively small changes in pressure. A vein has a normal elliptical configuration until the limit of its capacitance is reached, at which point the vein assumes a round configuration.

The calf muscles augment venous return by functioning as a pump. In the supine state, the resting venous pressure in the foot is the sum of the residual kinetic energy minus the resistance in the arterioles and precapillary sphincters. Thus, a pressure gradient is generated to the right atrium of approximately 10 to 12 mm Hg. In the upright position, the resting venous pressure of the foot reflects the hydrostatic pressure from the upright column of blood extending from the right atrium to the foot.

The return of the blood to the heart from the lower extremity is facilitated by the muscle pump function of the calf, a mechanism whereby the calf muscle, functioning as a bellows during exercise, compresses the gastrocnemius and soleal sinuses and propels the blood toward the heart. The normally functioning valves in the venous system prevent retrograde flow; when one or more of these valves become incompetent, symptoms of venous insufficiency can develop. During calf muscle contraction, the venous pressures of the foot and ankle drop dramatically. The pressures developing in the muscle compartments during exercise range from 150 to 200 mm Hg, and when there is failure of perforating veins, these high pressures are transmitted to the superficial system.

VENOUS INSUFFICIENCY

Chronic venous insufficiency (CVI) is dominated by venous reflux through incompetent venous valves. There are three categories of venous insufficiency—congenital, primary, and secondary. Congenital venous insufficiency comprises predominantly anatomic variants that are present at birth. Examples of congenital venous anomalies include venous ectasias, absence of venous valves, and syndromes such as Klippel-Trénaunay syndrome. Although secondary venous insufficiency can be considered a sequela of a previous acute thrombotic disorder (postthrombotic syndrome [PTS]), the etiology of primary CVI cannot be clearly identified.

Risk Factors

Risk factors for the development of varicose veins include advancing age, female sex, multiparity, heredity, history of trauma to the extremity, and prolonged standing. Additional risk factors include obesity and a positive family history. Advancing age appears to be an important significant risk factor. Venous function is undoubtedly influenced by hormonal changes. In particular, progesterone liberated by the corpus luteum stabilizes the uterus by causing the relaxation of smooth muscle fibers.[2] This directly influences venous function. The result is passive venous dilation, which in many cases causes valvular dysfunction. Although progesterone is implicated in the first appearance of varicosities in pregnancy, estrogen also has profound effects. It produces the relaxation of smooth muscle and a softening of collagen fibers. Furthermore, the estrogen-to-progesterone ratio influences venous distensibility. This ratio may explain the predominance of venous insufficiency symptoms on the first day of a menstrual period, when a profound shift occurs from the progesterone phase of the menstrual cycle to the estrogen phase. Autosomal dominant penetrance has been identified as the underlying genetic risk factor for subsequent development of varicose veins.

Pathology

Venous reflux through incompetent venous valves has been described as the main pathogenetic factor underlying CVI. However, obstruction of venous channels, resulting from intrinsic narrowing, postthrombotic thickening and scarring, or external compression, may also result in venous hypertension leading to CVI. In many cases, particularly after venous thrombosis, obstruction and reflux, coexist resulting in severe CVI.

Mechanical Abnormalities

Anatomic differences in the location of the superficial veins of the lower extremities may contribute to the pathogenesis. Primary venous insufficiency may involve one, both, or none of the axial veins (great and small saphenous). Perforating veins may be the sole source of venous pathophysiologic changes, perhaps because the GSV is supported by a well-developed medial fibromuscular layer and fibrous connective tissue that bind it to the deep fascia. In contrast, tributaries to the SSV are less supported in the subcutaneous fat and are superficial to the membranous layer of superficial fascia (Fig. 108.4). These tributaries also contain less muscle mass in their walls. Thus, these veins, and not the main trunk, may become selectively varicose.

When these fundamental anatomic peculiarities are recognized, the intrinsic competence or incompetence of the valve system becomes important. For example, failure of a valve protecting a tributary vein from the pressures of the SSV allows a cluster of varicosities to develop. Furthermore, communicating veins connecting the deep with the superficial compartment may have valve failure. Pressure studies have shown that there are two sources of venous hypertension. The first is gravitational and is a result of venous blood coursing in a distal direction down linear axial venous segments. This is referred to as *hydrostatic pressure* and is the weight of the blood column from the right atrium. The highest pressure generated by this mechanism is evident at the ankle and foot, where measurements are expressed in centimeters of water or millimeters of mercury.

The second source of venous hypertension is dynamic. It is the force of muscle contraction, usually contained within the compartments of the leg. If a perforating vein fails, high pressures (range, 150–200 mm Hg) developed within the muscular compartments during exercise are transmitted directly to the superficial venous system. Here, the sudden pressure transmitted causes dilation and lengthening of the superficial veins. Progressive distal valvular incompetence may occur. If proximal valves such as the saphenofemoral valve become incompetent, systolic muscular contraction is supplemented by the weight of the static column of blood from the heart. Furthermore, this static column becomes a barrier. Blood flowing proximally through the femoral vein spills into the saphenous vein and flows distally. As it refluxes distally through progressively incompetent valves, it is returned through perforating veins to the deep veins. Here, it is conveyed once again to the femoral veins, only to be recycled distally. Regardless of the precise source of the elevated hydrostatic pressure, the ultimate result is increased ambulatory venous hypertension.

A number of authors have demonstrated that the development of all the clinical manifestations of CVI can be ascribed to a blood flow–driven inflammatory process. Leukocytes are activated and marginalize. Adhesion to the endothelium is prompted by the expression of adhesion molecules, such as intracellular adhesion molecule 1 (ICAM-1), vascular cell adhesion molecule 1 (VCAM-1), and L- and P-selectins. Ultimately, they infiltrate the venous wall, lyse, and release activated extracellular matrix enzymes (matrix metallopeptidase [MMP]1, MMP2, and MMP9).[3] The extracellular matrix is degraded, and the venous wall, including the valves, undergoes remodeling. Decreased amounts of elastin and

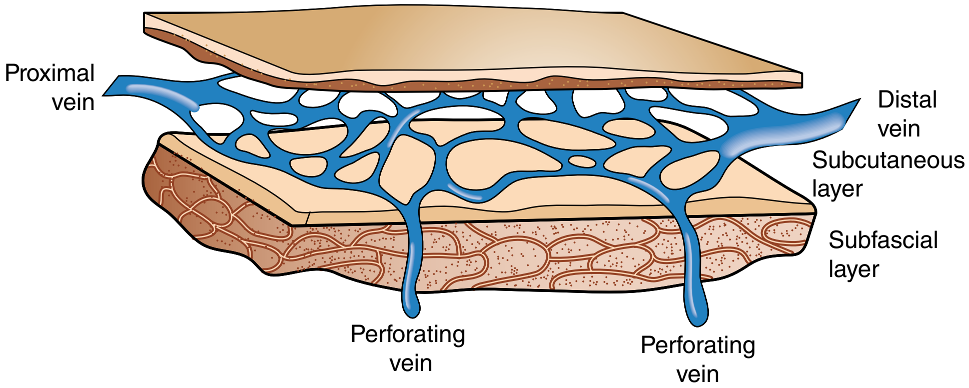

FIGURE 108.4 Dilation of superficial venous tributaries caused by increased transmission of pressure by the perforating veins.

an imbalance between collagen I and III have been identified in surgical specimens, suggesting that the loss of the venous wall intimal architecture leads to dilation, tortuosity, and the formation of varicose veins.[2,4]

Symptoms

The patient with symptomatic varicose veins commonly reports heaviness, discomfort, and extremity fatigue in the affected lower extremity. The pain is characteristically dull, does not usually occur during recumbency, and is exacerbated by periods of prolonged standing. Swelling is commonly described. The discomforts of aching, heaviness, and fatigue are usually relieved by leg elevation or elastic support. Cutaneous burning, termed *venous neuropathy,* can also occur in patients with advanced venous insufficiency. Pruritus occurs from excess hemosiderin deposition and tends to be located at the distal calf or in areas of phlebitic varicose branch segments. Patients may report cramping pain that occurs during or after exercise and is relieved with rest and leg elevation. This syndrome is termed *venous claudication* and is a clinical manifestation of venous outflow obstruction or secondary venous insufficiency. Predominant causes of venous claudication include a history of deep venous thrombosis (DVT) and/or diagnosis of May-Thurner syndrome.

Multiparous female patients in their childbearing years may report a constellation of symptoms that involve varicosities of the leg in conjunction with chronic pelvic pain. The lower extremity symptoms may or may not be present. Additional symptoms include a feeling of bladder fullness with standing, dyspareunia, and chronic pelvic pain. This clinical picture suggests pelvic congestion syndrome. Because the differential diagnosis for pelvic pain is extensive, the diagnosis of pelvic venous congestion tends to be one of exclusion; diagnostic modalities to confirm its presence include magnetic resonance venous imaging (MRVI) of the pelvis and conventional pelvic venography, which can be both diagnostic and therapeutic.

Physical Examination

A comprehensive examination includes assessment of the arterial circulation. Briefly, palpation of the femoral, popliteal, dorsalis pedis, and posterior tibialis pulses is performed. Nonpalpable pulses necessitate further evaluation.

The venous examination includes assessment of the patient in the standing and supine positions. The examination room must be well lit and warm so that vasospasm does not occur, limiting a comprehensive evaluation. Standing increases venous hypertension and dilates veins, thereby facilitating examination. Patients with superficial axial incompetence commonly exhibit palpable GSVs (Fig. 108.5).

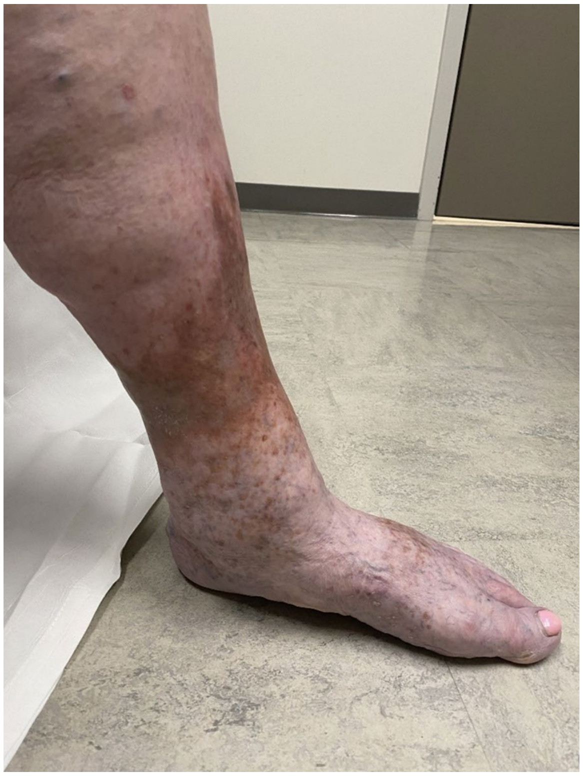

FIGURE 108.5 Hemosiderosis. (Courtesy C. Shokrzadeh, UTMB Galveston, Galveston, Texas.)

Visual inspection is critical. There are three main anatomic categories of primary venous insufficiency—telangiectasias, reticular veins, and varicose veins. Telangiectasias, reticular varicosities, and varicose veins are similar but exhibit distinct variations in caliber. Telangiectasias, commonly known as *spider veins,* are very small intradermal venules. These structures measure less than 1 mm. Without associated symptoms and stigmata of other venous disease, they are idiopathic in nature and are not medically necessary to treat.

Leg telangiectasias of multiple causes may be a manifestation of a systemic disease. Some of these disorders include autoimmune diseases (e.g., lupus erythematosus and dermatomyositis), exogenous causes, and xeroderma pigmentosum. Reticular veins are vein branches that enter the tributaries of the main axial, perforating, or deep veins. Reticular veins are larger than spider veins and usually have diameters between 1 and 3 mm. They are located in the subdermal or subcutaneous tissue. Varicose veins are located in the subcutaneous tissues and have diameters greater than 3 mm. The axial veins, the great and SSVs, represent the largest-caliber veins of the superficial venous system.

Location of varicosities can commonly identify an incompetent valve or the axial vein from which the varicosities developed. For example, medial thigh varicose veins are likely to develop from an incompetent GSV, whereas posterior calf or lateral calf varicose veins tend to originate from the SSV. In addition, the location of varicose veins can be a diagnostic predictor of a larger process. Varicosities of the scrotum can be associated with gonadal vein incompetence, otherwise termed the *nutcracker syndrome* (compression of the left renal vein between the aorta and the superior mesenteric artery). Perineal or vulvar varicosities can be a sign of ovarian or pelvic venous insufficiency or iliac vein obstruction.

The physical examination can provide the physician with important information on the history of the venous disease that the patient might have neglected or forgotten to mention during the history. For example, signs of a chronic or resolved thrombophlebitis may include a partially thrombosed varicosity; a brownish discoloration around a varicosity or along a palpable segment of the axial veins, consistent with hemosiderin deposition; and palpable segments of axial vein, suggesting partially or completely occluded axial vein segments.

Signs of advanced venous insufficiency include hyperpigmentation in the distal calf or gaiter distribution, secondary to hemosiderin deposition, and lipodermatosclerosis (Fig. 108.6A). Lipodermatosclerosis develops over time because of prolonged ambulatory venous hypertension and chronic inflammation.

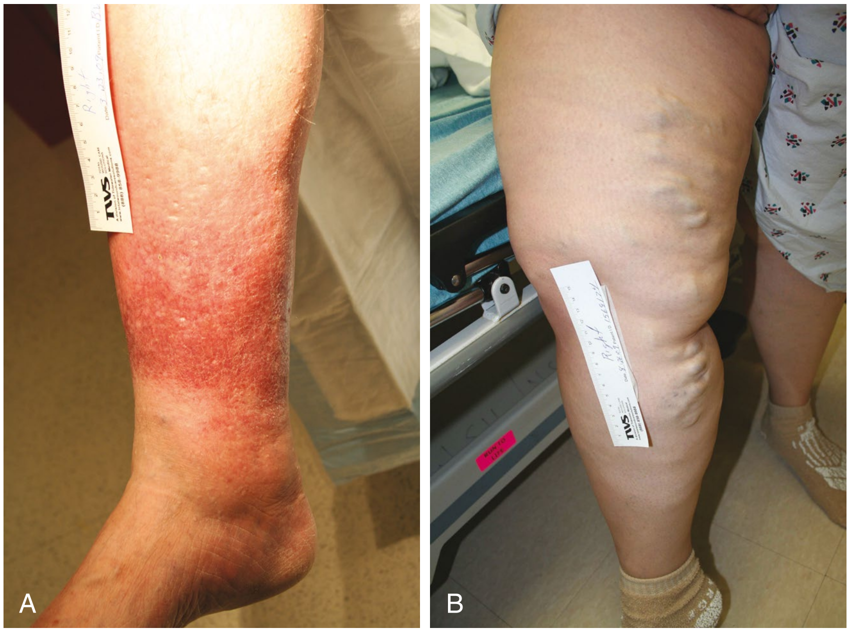

FIGURE 108.6 (A) Lipodermatosclerosis, hyperpigmentation and brawny edema. (B) Varicose vein.

Physical examination findings that reflect lipodermatosclerosis are brawny edema of the distal calf, "champagne bottle leg," fibrotic and hypertrophic skin, and hyperpigmentation. Advanced lipodermatosclerosis may involve fibrosis of the Achilles tendon, impairing motor function of the extremity. Therefore, examination should include motor function at the ankle. Atrophie blanche is an area of pale hue visualized around the medial malleolus; it is commonly mistaken for a healed ulcer because of its lighter pigmentation. *Corona phlebectatica* is a term used to describe an accumulation of tiny telangiectasias or venous flare, usually located at the medial malleolus or the dorsum of the foot. Skin changes from CVI can mimic other dermatologic phenomena; both dermatitis and eczematous changes can be seen in venous disease.

Venous stasis ulcers exhibit pathognomonic features that distinguish them from their arterial or neuropathic counterparts. Venous ulcers appear at the medial malleolus, not in the mid- to distal foot. Venous stasis dermatitis is visualized at the distal ankle and can mimic eczema or dermatitis of another cause. It is this important attention to supporting features of the physical examination and history as well as confirmation with duplex reflux examination that will distinguish advanced venous stasis disease from dermatologic conditions.

Diagnostic Evaluation of Venous Dysfunction

The Society for Vascular Surgery (SVS), the American Venous Forum (AVF), and the American Vein and Lymphatic Society (AVLS) have jointly released an update on the practice guidelines for the care of patients with CVI.[5] The Perthes test for deep venous occlusion and the Brodie-Trendelenburg test of axial reflux have been replaced by in-office use of the continuous-wave, handheld Doppler instrument supplemented by duplex ultrasound evaluation. The handheld Doppler instrument can confirm an impression of saphenous reflux, which in turn dictates the operative procedure to be performed in any given patient. A common misconception is the belief that the Doppler instrument is used to locate perforating veins. Instead, it is used in specific locations to determine incompetent valves—for example, the handheld, continuous-wave, 8-MHz flow detector placed over the great and SSVs near their terminations. With distal augmentation of flow and release, normal deep breathing, and performance of a Valsalva maneuver, valve reflux is accurately identified. Formerly, the Doppler examination was supplemented by other objective studies, including photoplethysmography, mercury strain-gauge plethysmography, and photorheography. These are no longer in common use.

Today, duplex imaging is the first and best modality to assess for the normal function and presence of venous insufficiency of the lower extremities. Duplex technology more precisely defines which veins are refluxing by imaging the superficial and deep veins. The SVS/AVF/AVLS clinical practice guidelines detailed four crucial components of the duplex examination: visibility, compressibility, venous flow, and augmentation.[5] It is important to note that venous reflux duplex done with the patient supine yields an erroneous evaluation of reflux. In the supine position, even when no flow is present, the valves remain open. Valve closure requires a reversal of flow with a pressure gradient that is higher proximally than distally. Thus, the duplex examination needs to be done with the patient standing or in the markedly trunk-elevated position.[6]

There are many advantages of ultrasound imaging. The ultrasound examination is noninvasive, requires no contrast material, and can be performed in the office as well as in the hospital. Drawbacks to the modality include interobserver variability and limitations in imaging in patients with an elevated body mass index and extensive dressings. Imaging is obtained with a 7.5- or 10-MHz probe; the pulsed Doppler consists of a 3.0-MHz probe. The examination begins with the probe placed longitudinally on the groin. First, all the deep veins are examined. Next, the superficial veins are evaluated. There are four basic components of the examination that should be included to complete a comprehensive venous evaluation of the lower extremity veins: compressibility, venous flow, augmentation after reflux, and visibility. Reflux can be demonstrated with the patient performing a Valsalva maneuver or by manual compression and release of the extremity distal to the point of the examination. A Valsalva maneuver is performed for the proximal extremity—that is, the thigh and groin—whereas compression is used for the calf. Reflux times of 500 milliseconds or longer are considered significant in the axial veins. Perforator veins can be visualized well with the duplex examination (Fig. 108.7). Significant perforator reflux is defined as a diameter of more than 3.5 mm and a reflux time of 350 milliseconds or longer. Demonstration on duplex images of to-and-fro flow, with the presence of dilated segments, constitutes findings compatible with a refluxing perforator. In addition, Doppler studies can provide the clinician with information about the deep system. Reflux times of 1000 milliseconds or longer are considered significant in the femoropopliteal veins. Widespread use of duplex scanning has allowed a comparison of findings between standard clinical examinations and duplex Doppler studies.[7,8]

Phlebography and Venography

In general, phlebography is unnecessary in the diagnosis and treatment of primary venous insufficiency. In cases of secondary CVI, phlebography has specific usefulness. Ascending phlebography is performed by injection of contrast material into a superficial pedal vein after a tourniquet is applied at the ankle to prevent flow into the superficial venous system. Observation of flow defines anatomy and regions of thrombus or obstruction. Therefore, ascending phlebology differentiates primary from secondary venous insufficiency. Descending phlebography is performed with retrograde injection of contrast material into the deep venous system at the groin or popliteal fossa (femoral vein or popliteal vein). This diagnostic modality identifies specific valvular incompetence suspected on B-mode scanning and clinical examination. However, these invasive studies are seldom performed and are used only as preoperative adjuncts when deep venous reconstruction is being planned.

Magnetic Resonance and Computed Tomography Venous Imaging

Advancements in technology have led to a paradigm change in the imaging of the venous system. MRVI is a diagnostic imaging modality reserved for evaluation of the abdominal and pelvic venous vasculature. MRVI, unlike venography, is noninvasive and does not require intravenous (IV) administration of contrast material. Studies have documented similar rates of specificity and sensitivity compared with venography. MRVI is used to evaluate pelvic venous outflow obstruction, providing information from the IVC through the iliac venous system. Furthermore, it is an excellent test to evaluate for pelvic congestion syndrome. Computed tomography venography (CTV) has similar applications to MRVI. A large meta-analysis showed that CTV has sensitivity from 71% to 100% and specificity ranging from 93% to 100% for the diagnosis of proximal DVT. Anatomy of the abdominal and pelvic venous system can be well characterized by CTV. Limitations may include artifacts from orthopedic implants and/or adjacent pathology, administration of contrast, and pelvic radiation in young patients.

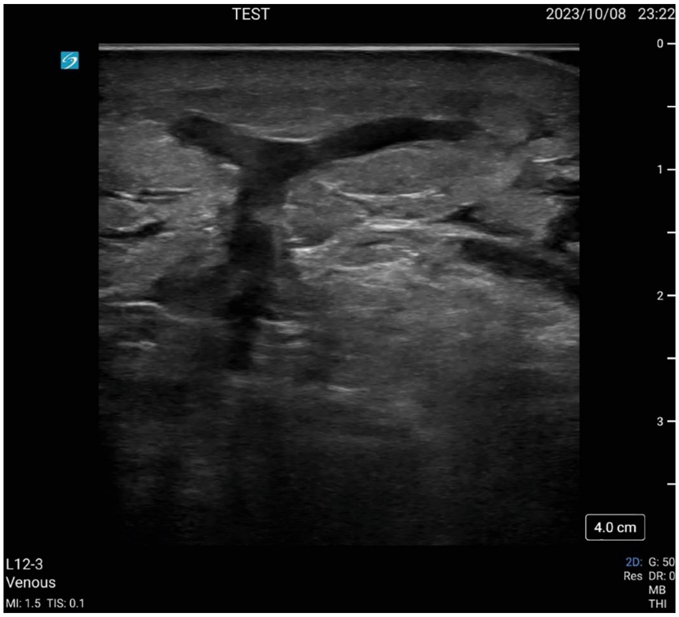

FIGURE 108.7 Calf perforator vein on ultrasound. (Courtesy C. Shokrzadeh, UTMB Galveston, Galveston, Texas.)

Classification Systems

In 1994, the AVF devised the Clinical-Etiological-Anatomical-Pathophysiological (CEAP) classification system, which is a scoring system that stratifies venous disease on the basis of clinical presentation, etiology, anatomy, and pathophysiology (Table 108.3). It is useful in helping the physician assess a limb afflicted with venous insufficiency and then arrive at an appropriate treatment plan. A revised CEAP classification was introduced in 2004 that included a Venous Disability Score to document a patient's ability to perform activities of daily living.[9] In 2020, the CEAP classification system was further updated to include corona phlebectatica as a clinical subclass, introducing the modifier "r" for recurrent varicose veins and recurrent venous ulcers and replacing numeric descriptions of the venous segments with their common abbreviations. Although the CEAP classification is a valuable tool to grade venous disease, assessment of outcomes after intervention cannot be realized. As a result, two additional scoring systems, the Venous Clinical Severity Score and the Venous Segmental Disease Score, enhance the CEAP score with the increased ability to plot outcome. These three classification modalities now provide clinical researchers with invaluable tools to study treatment outcomes.[10]

Treatment of Superficial Venous Insufficiency

Nonoperative Management

Nonoperative management of patients with CVI includes lifestyle modifications, compression, and pharmacologic therapies.[10] Initial recommendations for lifestyle changes are avoidance of vigorous exercise and leg elevation in order to improve symptoms caused by venous hypertension. Although vigorous exercise has been shown to increase the risk of developing venous ulcerations, increased mobility and moderate physical activity may be beneficial for ulcer healing and may be a useful adjunct to compression therapy. Leg elevation 30 cm above the heart aids venous drainage and venous return, thus reducing lower extremity venous edema. Leg elevation has also been shown to enhance cutaneous microcirculation in patients with lipodermatosclerosis (45% Doppler flux increase).[10] A retrospective study of 122 patients with healed venous ulcer over a period of 12 to 40 months documented statistically significant lower rates of ulcer recurrence with a combination of compression therapy and longer leg elevation times (median 33 min/day). Increased recurrence was observed with a median period of leg elevation of 14 min/day.[10]

Compression therapy is an integral component of the care of patients with CVI. The rationale of compression therapy is to

TABLE 108.3 Classification of Chronic Lower Extremity Venous Disease

CLINICAL (C) CLASS	DESCRIPTION
C_0	No visible or palpable signs of venous disease
C_1	Telangiectasias or reticular veins
C_1	Varicose veins
C_2	Recurrent varicose veins
C2r	Edema
C4	Changes in skin and subcutaneous tissues secondary to CVD

CVD, Chronic venous disease.

Based on Lurie F, Passman M, Meisner M, et al. The 2020 update of the CEAP classification system and reporting standards. *J Vasc Surg Venous Lymphat Disord.* 2020;8(3):342-352.

oppose the reflux-induced venous hypertension. Considering 60 to 80 mm Hg to be within normal limits for standing venous pressure, hemodynamic effects can be expected with an interface compression of 30 to 40 mm Hg. External compression of greater than 60 mm Hg has been shown to occlude lower extremity veins in standing individuals. Investigations conducted via dermal blood flow assessment have demonstrated that compression rates of 30 to 40 mm Hg are also beneficial in patients with combined chronic venous disease and peripheral arterial disease with ankle-brachial indexes greater than 0.5. The biomolecular mechanisms by which compression therapy functions are unclear. Animal and clinical studies have described an overall improvement of the cutaneous microcirculation; increased capillary density, decreased capillary diameter, and pericapillary halo at video capillary microscopy; increased transcutaneous oxygen saturation levels; and decreased levels of cytokines, such as tumor necrosis factor α and vascular endothelial growth factors.[10]

Compression therapy can be achieved via gradient compression stockings and bandages. Gradient elastic stockings are considered the most initial intervention in patients with clinical stigma of venous disease. They are currently available in four tensions: 10 to 15 mm Hg (class 1; over the counter); 20 to 30 mm Hg (class 2; prescription); 30 to 40 mm Hg (class 3; prescription); and 40 to 50 mm Hg (class 4 high compression; prescription). They are also available in different sizes and lengths. Gradient compression stockings have been shown to be beneficial in symptom control in patients with moderate CVI.[10] Sequential compression devices (SCDs) can also serve as an adjunct to traditional compression therapy provided by compression stockings and bandages. Studies have shown that consistent usage of sequential pneumatic compression therapy improves pain level and quality of life.[11]

Patients who exhibit venous stasis ulceration will require local wound care (see Fig. 108.7). A triple-layer compression dressing with a zinc oxide paste gauze wrap in contact with the skin is used most commonly from the base of the toes to the anterior tibial tubercle with snug, graded compression. This is an example of what is generally known as an *Unna boot.* A 15-year review of 998 patients with one or more venous ulcers treated with a similar compression bandage demonstrated that 73% of the ulcers healed in patients who returned for care (Fig. 108.8). The median time to healing for individual ulcers was 9 weeks. In general, snug, graded-pressure, triple-layer compression dressings result in more rapid healing than compression stockings alone.[12]

For most patients, well-applied, sustained compression therapy offers the most cost-effective and efficacious therapy in the healing of venous ulcers. After healing, most cases of CVI are controlled with elastic compression stockings to be worn during waking hours. On occasion, older patients and those with arthritic conditions cannot apply the compression stocking required, and control must be maintained by triple-layer zinc oxide compression dressings, which can usually be left in place and changed once a week. Donning devices are also available on the market to help patients to apply compression stockings. In addition to compression, wound care, and surgery, large chronic venous ulcers may benefit from venoactive medications, in particular, pentoxifylline and micronized purified flavonoid fraction.

The 2022 clinical practice guideline recommends superficial venous intervention over long-term compression in patients who suffer from symptomatic varicose veins and axial reflux in the GSV or SSV. After clinical and objective criteria have established the presence of symptomatic varicose veins, the next step is to plan a course of therapy. The Eschar Trial randomized 500

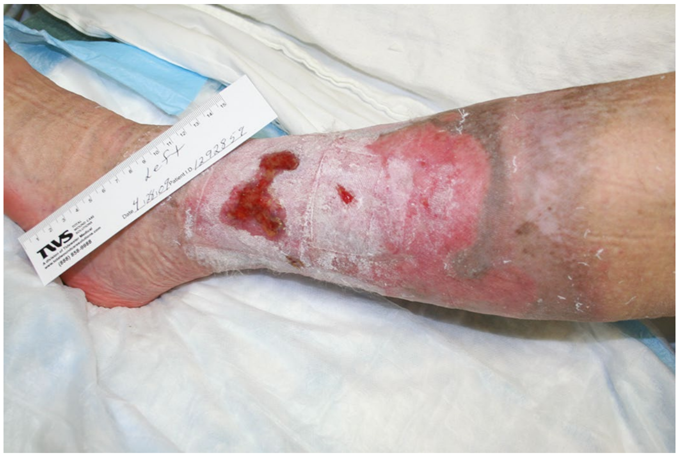

FIGURE 108.8 Venous stasis ulcer.

patients with saphenous insufficiency and venous leg ulcers to conservative management with compression therapy or saphenous stripping and compression therapy. At 4 years of follow-up, there was no evidence of a significant difference in ulcer healing rates, but the incidence of ulcer recurrence after healing was significantly lower in patients who underwent saphenous stripping.[10,12] Recent prospective randomized control trials focusing on the effectiveness of endovenous therapies that are considerably less invasive have shown significantly improved ulcer healing rates in patients who have undergone radiofrequency ablation (RFA) of insufficient saphenous veins compared with compression bandages alone.[13]

Treatment Options for Telangiectasias

Telangiectasias and reticular veins are usually treated in the outpatient setting. Asymptomatic telangiectasias and reticular veins are of cosmetic concern only. In these asymptomatic patients with only C_1 disease, a reflux examination is not indicated. However, if the patient describes symptoms consistent with possible venous insufficiency or has concomitant varicosities or more advanced disease on physical examination, a reflux examination is indicated. Treatment options for telangiectasias (spider veins and reticular veins) include injection sclerotherapy and transdermal laser treatment (Fig. 108.9).

Injection sclerotherapy is a technique that involves direct injection of a sclerosant agent into the feeding vein (reticular vein) or spider vein. This procedure is performed in the office setting. There is no preprocedural preparation of the patient. However, patients are asked not to shave or apply lotions to the extremity before the treatment. Patients leave the office and are able to perform regular activities immediately. Direct sunlight exposure to the treatment area is avoided for a few weeks after the injection. Although it is a safe technique, injection sclerotherapy is contraindicated in the following situations: pregnancy, patients with acute superficial thrombophlebitis (SVT), patients with acute DVT, patent foramen ovale with right-to-left heart shunt, severe arterial occlusive disease in the treated extremities, and patients with a history of severe allergy or severe asthma.

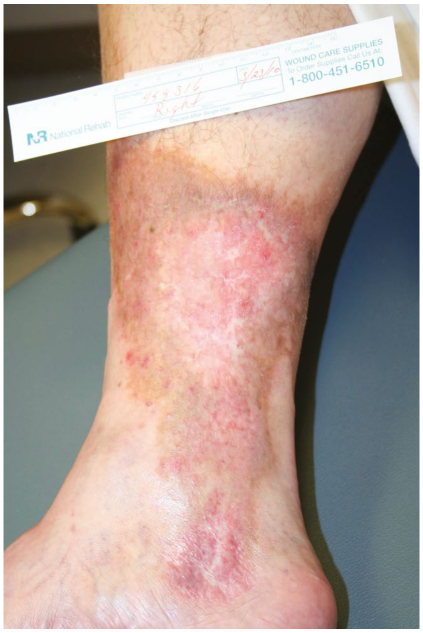

FIGURE 108.9 Healed venous stasis ulcer.

Sclerosants act to disrupt the venous endothelium, causing a periphlebitic reaction, which acts to obliterate the vein segment. There are many sclerosants available, and there are particular categories of sclerosants. They include osmotic, detergent, chemical, and corrosive. Hypertonic saline, in various concentrations, was long considered the agent of choice; however, it can be painful with injection (despite the addition of local anesthetics) and appears to exhibit a higher incidence of hyperpigmentation after treatment. Therefore, varying concentrations of sodium tetradecyl sulfate (Sotradecol) and polidocanol (Asclera, Varithena) are now the preferred agents.

The procedure should be performed in a well-lit room. Dilute solutions of sclerosant (e.g., 1%–3% sodium tetradecyl sulfate; polidocanol 0.5%, 1%, 1.5%) can be injected directly into the venules. Care must be taken to ensure that no single injection dose exceeds 0.1 mL but that multiple injections completely fill all feeding vessels. Larger spider veins should be injected first. Injection should begin proximally and proceed distally. When the session is complete, a pressure dressing is applied, consisting of cotton balls at each injection site, and then covered with compression stockings or elastic bandages. Patients are advised to ambulate frequently during the first 24 hours and abstain from direct sun exposure and airline travel for 2 weeks. On occasion, entrapped blood may form, and patients report significant discomfort. Needle drainage is performed at the site, which facilitates healing and cosmesis and rapidly improves discomfort. This liberation of entrapped blood is as important to success as the primary injection. This therapy is remarkably successful in achieving an excellent cosmetic result. C_1 larger than 1 mm and smaller than 3 mm can also be injected with a sclerosant of slightly greater concentration, but the amount injected at one site needs to be limited to less than 0.5 mL. A total volume of sclerosant should not exceed 4 mL during a treatment session. If one is using hypertonic saline, maximum treatment volume can be 10 mL. Although injection sclerotherapy has met with significant success, complications do occur. They include hyperpigmentation, venous matting, post-sclerotherapy necrosis, and an allergic reaction to the sclerosant. In addition, telangiectasia formation after injection sclerotherapy treatment tends to occur. Patients will commonly observe return of spider veins 8 to 12 months after treatment. Although patients may report localized discomfort, sclerotherapy of telangiectasias is considered cosmetic and does not influence the venous circulation of the extremity.[14]

Laser treatment of spider telangiectasias has been performed with a variety of wavelengths and varying techniques, such as high-intensity pulsed light, fiber-guided laser coagulation, and neodymium:yttrium-aluminium-garnet (ND-YAG) laser with a wavelength of 1064 nm. Evaluation of all existing laser modalities has suggested that the ND-YAG laser has the most success. However, to date, there have not been any prospective randomized trials to support this presumption. Laser treatment does tend to be more painful. Laser treatment in most centers will be used in conjunction with injection sclerotherapy—that is, injection treats the feeding venules; laser treatment will be used to treat the extremely small branches not adequately addressed with the injection technique. Most patients are satisfied with the injection-only method.

Surgery for Axial Venous Incompetence

Vein stripping. It has been more than a century since surgeons began to develop techniques to treat superficial axial venous reflux. Keller introduced saphenous vein invagination and stripping, and

Mayo pioneered use of an external stripper to remove the saphenous vein. Babcock described stripping the saphenous vein intraluminally from the ankle to groin. High ligation of the GSV was also described; however, it proved to be ineffective because the refluxing axial vein was not eliminated. Although effective, stripping of the GSV is now rarely performed, given its high morbidity. Endovenous thermal ablation procedures with radiofrequency or laser and nonthermal ablation with chemical sclerosant have replaced stripping in the past two decades and are now the mainstay of treatment for refluxing axial veins. Traditional vein stripping usually requires general or spinal anesthesia. A transverse or oblique groin incision is made just medial to the femoral artery pulse and inferior to the inguinal crease. Sharp dissection allows identification of the proximal GSV and other venous tributaries that can be ligated and divided. A brief exploration to identify the presence of a duplicate saphenous system should be performed. The GSV can then be brought up into the surgical field with gentle traction on the SFJ. This maneuver affords further visualization of any missed tributaries that require ligation. The GSV should be ligated with a nonabsorbable suture and transected near its confluence with the femoral vein. Attention is then directed to the below-knee segment of the GSV by making a small transverse incision on the proximal, medial calf. The GSV is identified, ligated distally, and transected. The Codman stripper is then advanced proximally through the GSV to exit the transected vein in the groin incision. The bulb is attached to the end of the Codman stripper that exits the groin incision, and a handle is attached to the other end (exiting the calf incision). The saphenous vein should be secured to the bulb of the stripper and inverted onto itself. Forcefully pulling on the handle of the Codman stripper removes the GSV from the groin to the knee. Before stripping, the lower extremity should be wrapped circumferentially to aid in hemostasis and prevent postoperative edema and permanent hyperpigmentation resulting from blood extravasation.

Complications. *Neovascularization* refers to the development of new venous tributaries and varicose veins around the previously ligated and divided SFJ. The incidence of neovascularization after high ligation and stripping of the GSV exceeds 30%, according to some reports. Interestingly, neovascularization does not occur after endovenous ablation procedures, which obviate the need for a groin dissection or venous tributary ligation. Rather than being beneficial, surgical dissection and tributary ligation may actually trigger neovascularization and varicose vein recurrence. Monitoring for this complication usually involves periodic duplex ultrasound examination.

Saphenous nerve injury is a well-documented complication that occurs more frequently when the GSV is stripped from the ankle to the groin. The saphenous nerve runs close to the GSV in the calf compared with the thigh, where the nerve and vein have more separation. This anatomic detail may explain why stripping from the knee to the thigh only reduces the risk of nerve injury (Fig. 108.10). Stripping of the SSV has also been described; however, it carries a very high risk of nerve injury, given the proximity of the sural nerve in the posterior aspect of the leg. Therefore, because of the several limitations and disadvantages of stripping of the GSV, it has been replaced by endovenous techniques. Percutaneous endovenous ablation procedures include thermal and nonthermal ablations.

Endovenous thermal and nonthermal ablation. Percutaneous endovenous ablation of the superficial axial veins revolutionized the treatment of superficial venous insufficiency and has been the mainstay of treatment for more than two decades. As a minimally invasive alternative to surgical vein stripping, percutaneous endovenous ablation can be performed on an outpatient basis with local anesthesia. Advantages of this technique include less discomfort for the patient and a more rapid recovery. There are two main types of endovenous thermal therapy for the superficial axial veins: RFA and endovenous laser therapy (EVLT). Both of these modalities generate high yet focused temperatures to prevent injury to surrounding tissues. Endovenous thermal ablation works by destruction of the venous endothelium and collagen in the medial via direct thermal injury. Tumescent fluid is required for these thermal ablation techniques for anesthesia and also functions as a heat sink.

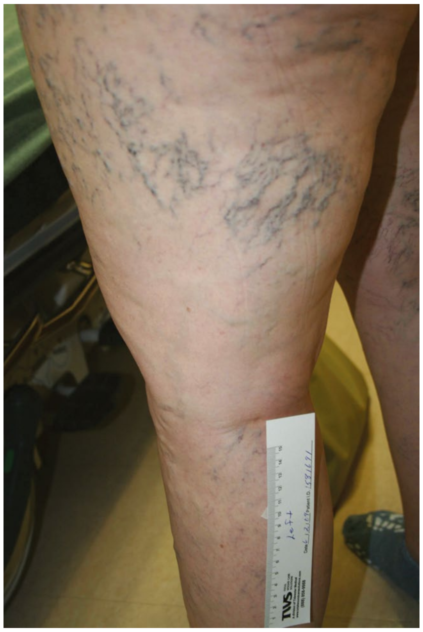

FIGURE 108.10 Spider telangiectasias.

In contrast, nonthermal ablation techniques exist and are also known as *nontumescent endovenous ablation modalities* because they do not require tumescent anesthesia. The three major nonthermal ablation techniques are mechanochemical ablation (MOCA), cyanoacrylate adhesive closure (CAC), and polidocanol endovenous microfoam (PEM). These procedures are sometimes favored over thermal ablation for the treatment of SSV and the below-knee segment of the GSV because of the reduced likelihood of nerve damage.

Percutaneous vein ablation. Endovenous thermal ablation, as well as nonthermal techniques, requires minimal preprocedural preparation. Healthy patients with no significant medical history do not require laboratory work, whereas standard laboratory evaluation is usually obtained for patients with significant medical comorbidities. Patients who are receiving anticoagulation should remain on their standard regimen. Guidelines for periprocedural DVT prophylaxis remain unclear. All antiplatelet medications can be continued throughout the procedural course. The authors do not routinely administer prophylactic antibiotics.

Anesthesia for endovenous thermal ablation procedures can range from local injections to conscious sedation. Most patients tolerate the procedure with minimal anesthesia consisting only of tumescent infusion around the GSV. Ideally, these patients can be treated in an office setting. Moderate sedation requires hemodynamic monitoring equipment and is more suited for an outpatient surgical center. The choice of anesthesia ultimately depends on the preferences of the patient and physician as well as the available resources and practice environments.

The venous duplex ultrasound examination plays an essential role in planning of endovenous ablation procedures. The ultrasound examination should provide the treating physician with the following information: patency of the deep venous system, location of normal and refluxing axial veins, areas of communication between the varicosities and the axial vein, and presence of duplicate or accessory refluxing vein segments.

An acute occlusive DVT is an absolute contraindication to endovenous thermal and nonthermal ablation, whereas a chronically recanalized deep venous system in the extremity to be treated is a relative contraindication. In patients who harbor secondary venous insufficiency, the superficial veins play a more important role in venous drainage compared with patients with a pristine deep venous system and primary venous insufficiency. Care must be taken to ensure that superficial venous ablation will not compromise the venous outflow of the postthrombotic limb.

The site of percutaneous access depends on the patient's symptoms and the location of the varicose vein tributaries. If endovenous thermal ablation of the GSV is planned in a patient with painful varicosities on the proximal calf, it is helpful to evaluate these branches with ultrasound. Percutaneous access on the distal calf just inferior to the varicose veins will ensure that maximum resolution of the tributary branches is achieved with endovenous thermal treatment.

RFA and laser energy deliver two different types of energy to the vein lumen. Radiofrequency heat is delivered at a temperature of 120°C. The radiofrequency directly injures the vein wall endothelium, resulting in collagen contraction and thrombosis of the treated vein. Laser energy delivers energy to the blood itself. Steam bubbles are generated with the laser energy, and coagulation occurs after completion of laser energy delivery. Radiofrequency catheters vary in length but not in temperature delivered. In contrast, laser energy generators come in different wavelengths ranging from 810 to 1470 nm, and there are multiple wavelengths commercially available; as such, updated laser therapy strategies are frequently introduced into the evolving therapeutic armamentarium. Investigators have demonstrated that the higher-wavelength fibers appear to be associated with less postprocedural discomfort.

Technique. In most cases, the extremity should be placed in a position of external rotation with the knee slightly flexed. A sheet "bump" or pillow behind the hip and knee may help the patient maintain this position. Placing the patient in reverse Trendelenburg can help dilate the vein to be accessed. After the standard sterile preparation and draping, the ultrasound probe is brought onto the field in a sterile transducer cover. The author reexamines the vein to be treated along its entire course, noting areas of aneurysmal dilation or tortuosity that may affect catheter placement. Ideally, the puncture site should be distal to the lowest level of truncal reflux and provide unobstructed access to the refluxing vein segment.

At the chosen site of percutaneous access, the ultrasound probe is positioned to obtain a stable gray-scale image of the vein in either the transverse or sagittal plane. Local anesthetic is often injected at the intended site of access. The author prefers the micropuncture system for gaining access while using ultrasound guidance. On real-time imaging, the needle is guided into the vein lumen and exchanged over a wire for a 4-Fr micropuncture sheath. The wire is then exchanged for an 0.035 wire, which will be used to upsize the sheath to a 6- or 7-Fr sheath using the modified Seldinger technique. With ultrasound guidance, the radiofrequency catheter or laser catheter is then advanced through the sheath, and the ultrasound probe is positioned in the groin to visualize the catheter tip, the SFJ, and the deep system. Using ultrasound guidance, the tip of the ablation catheter is placed 2 to 3 cm distal to the SFJ to minimize the chance of heat transmission into the femoral vein. Definitive positioning of the therapeutic catheter must be completed at this point before the administration of local anesthesia during the next stage of the procedure. Imaging artifacts from the tumescent anesthesia tends to impede visualization of the catheter tip, making it difficult to adjust its position.

Before tumescent anesthesia is begun, the patient should be placed in the Trendelenburg position to help empty the vein. Tumescent anesthesia is the infusion of a large volume of dilute local anesthetic. Although there are many recipes for tumescent solution, the main components are lidocaine, epinephrine, and sodium bicarbonate diluted with lactated Ringer solution or normal saline. During laser treatment and RFA procedures, tumescent anesthesia performs three functions: It provides anesthesia over a large area; it compresses the vein around the therapeutic catheter; and it acts as a protective barrier to prevent heating of nontarget tissues, including skin, nerves, arteries, and the deep veins.

For GSV procedures, the target of tumescent anesthesia is the saphenous sheath. When it is viewed in the transverse plane, the saphenous canal resembles an eye, and the ultrasound image is often referred to as the *saphenous eye*. Administration of tumescent anesthesia starts distally on the lower extremity and progresses proximally. Real-time ultrasound imaging guides a 21- to 25-gauge needle into the saphenous canal to deliver the tumescent anesthesia. When it is injected into the proper perivenous tissue plane, the tumescent anesthesia will track up and around the target vein. A long-axis ultrasound view gives the best image of fluid spreading up the saphenous canal. Multiple skin punctures and injections are performed until the vein has a 10-mm halo of tumescent anesthesia along its entire course, also known as the *target sign*. The targeted vein segment is then reinspected by ultrasound to ensure that the vein is compressed around the therapeutic catheter and adequately separated from the overlying skin.

Radiofrequency energy or laser energy is then applied to the vein segment by activating and slowly withdrawing the therapeutic catheter. The specifics of retrograde pullback depend on the type of catheter. Radiofrequency energy involves a segmental pullback governed by hash marks on the catheter and a timed activation on the accompanying generator. Laser energy catheters are variable; some have a slow, continuous pullback, whereas others require a segmental pullback. Gray-scale ultrasound images can often detect steam bubbles generated by the laser fiber.

Regardless of the type of energy delivered, once the vein has been completely treated, the sheath and accompanying catheter are removed. Ultrasound imaging resumes, confirming the patency of the femoral vein as well as successful occlusion of the GSV. Color Doppler imaging is often the only way to assess patency at this point because of the distortion caused by the ablation and the surrounding tumescent anesthesia. It is also important to verify retrograde epigastric venous flow into the proximal segment of the GSV. This provides a "protective flush" of the GSV. It is believed by many venous experts that this flow pattern prevents postprocedural development of endovenous heat-induced thrombus (EHIT).

Postprocedural instructions vary by practitioner. The patient's extremity is usually wrapped in a layered compression dressing, or a 20- to 30-mm Hg compression stocking is applied. The patient is instructed to walk every hour until bed. Regular activity, except for vigorous cardiovascular exercise, can be resumed the following day. After a satisfactory postprocedural duplex examination, all activity restrictions are lifted.

Most venous specialists recommend a physical examination or duplex ultrasound examination 2 to 5 days after the procedure. The duplex ultrasound examination ensures that the deep venous system remains patent and confirms the ablation of the GSV. Reported rates of DVT within 30 days after endovenous ablation range from 0% to 4% after RFA and 0% to 3% after laser ablation.[15] Although the incidence of postablation DVT is extremely low, duplex ultrasound examination can detect thrombus in the proximal GSV that can extend into the common femoral vein. Dr. Lowell Kabnick coined the term *endovenous heat-induced thrombus (EHIT)* to describe this ultrasound finding. He classified EHIT into four different levels based on the size of the thrombus and its extension into the deep venous system.

The mechanism of EHIT formation remains unclear. General consensus assumes that heat-triggered thrombus in the GSV propagates into the SFJ and encroaches on the deep venous system. EHIT and acute DVT differ in their sonographic characteristics and natural history. EHIT becomes sonographically echogenic quickly (<24 hours), whereas acute DVT usually remains hypoechoic for several days after its initial detection. Although EHIT appears to have a low propensity to propagate or embolize, pulmonary embolism (PE) has been reported after venous ablation procedures. Follow-up ultrasound examinations usually demonstrate retraction or complete resolution of EHIT within 7 to 10 days. Given this benign natural history, most practitioners do not treat class 1 and class 2 EHIT. Class 3 EHIT, which involves partial, nonocclusive extension into the deep venous system, usually warrants anticoagulation therapy, the duration of which can vary on the basis of the physician's discretion. Because class 4 EHIT represents occlusive DVT, it requires a 3-month course of anticoagulation.

The choice of whether to use RFA or laser as the energy source for venous ablation procedures remains a matter of the physician's preference. Randomized prospective studies comparing the two techniques have detected few differences. Patients treated with laser ablation tended to have more discomfort in the very early postprocedural period; however, all other outcome variables were similar.[16,17]

Nonthermal Ablation and Future Modalities for Axial Vein Incompetence

Endovenous nonthermal ablation techniques include MOCA, CAC, and PEM. These techniques all require ultrasound guidance for vein access, but no tumescence is required. Given their ease of operation, the majority of these procedures are performed in an outpatient clinic setting. MOCA involves the use of a catheter that combines endovenous chemical veinous destruction with a rotating wire and infusion of liquid sclerosant that causes inflammation to achieve closure of the treated vein. Ultrasound-guided sclerotherapy (UGS) targeted at the refluxing axial veins has also been described. It is mostly used for closure of large tributaries or varicose veins of the axial veins. Specific details about sclerosant preparation are outside the scope of this chapter. To reduce the amount of sclerosant used, physician-compounded foam is sometimes used.

Injectable PEM, Varithena, was approved by the US Food and Drug Administration in 2013 as a form of chemical ablation used for treatment of incompetent superficial veins. Studies have shown that treatment with a single administration of up to 15 mL of PEM results in significant improvement in alleviating venous insufficiency symptoms and resolution of varicose veins.[18] An advantage of PEM is the ability to treat varicose veins and refluxing tributaries of the saphenous vein at the same time as the axial vein treatment because the drug travels cephalad and easily distributes to other vein branches.

For the treatment of refluxing axial veins, the author uses the sterile technique. Because there is minimal risk of nerve injury, the access site can be selected as distally as possible, ideally at the vein segment that feeds into other varicose veins. The author prefers the micropuncture system for gaining access while using ultrasound guidance. Once the micropuncture sheath is placed within the vein, an appropriate amount of PEM is withdrawn from the canister and given through the sheath at intervals of 1 to 2 cc per second until all the drugs have been delivered. Care must be taken to mitigate risks of DVT extension, which usually has an incidence between 1.5% and 3%. Various techniques have been proposed to reduce the risk of DVT from PEM injection, which include elevation of limb >45 degrees during injection, ultrasound visualization and digital occlusion of perforator veins, injection of sterile saline before treatment, compression of the SFJ during treatment, and compression of limb in elevated position. Limiting the amount of PEM used can also decrease the risk of proximal thrombus extension and overall DVT risk.[18] The patient is instructed to ambulate and resume normal daily activities after treatment. Compression to the treated lower extremity is recommended for 2 weeks after treatment. Ultrasound of the treated vein and deep venous system is performed 2 to 5 days after the procedure to ensure appropriate closure of the treated vein and assess for any DVT.[18]

CAC is another nonthermal ablation modality that has gained popularity in treating insufficient axial veins in recent years as studies have demonstrated its clinical efficacy in vein closure. It uses ultrasound guidance for placement of a catheter that delivers a measured dose of cyanoacrylate glue to seal the vein. The treated vein is closed by the glue initially and, over time, will fibrose to keep the lumen closed. Similar to injectable PEM, it does not require tumescence because of its nonthermal nature. Therefore, access at the distal GSV or SSV around the ankle can be easily established without concern of nerve injury with a micropuncture system under ultrasound guidance. The sheath is upsized to a 7-Fr sheath into which the catheter is advanced to the SFJ. Under ultrasound, the catheter is then pulled 3 cm distal to the junction, and glue is applied in small aliquots at 2- to 3-cm intervals while continuous manual compression with the ultrasound probe at the SFJ is applied to avoid embolization to the deep venous system. Care is taken to capture the catheter within the sheath before the entire system is removed from the patient to avoid extravasation of the adhesive into the surrounding subcutaneous tissue. Allergic reactions to the adhesive, ranging from mild inflammation to necrosis of surrounding tissues, have been reported in patients. To minimize this risk of adverse reaction, patients are surveyed before the procedure to ensure they do not have any prior history of allergies to cyanoacrylates glue.[19]

Treatment of Branch Varicosities

There are three techniques to treat secondary branch varicosities: conventional stab phlebectomy, powered phlebectomy (TriVex; InaVein, Lexington, MA), and foam sclerotherapy (described earlier).

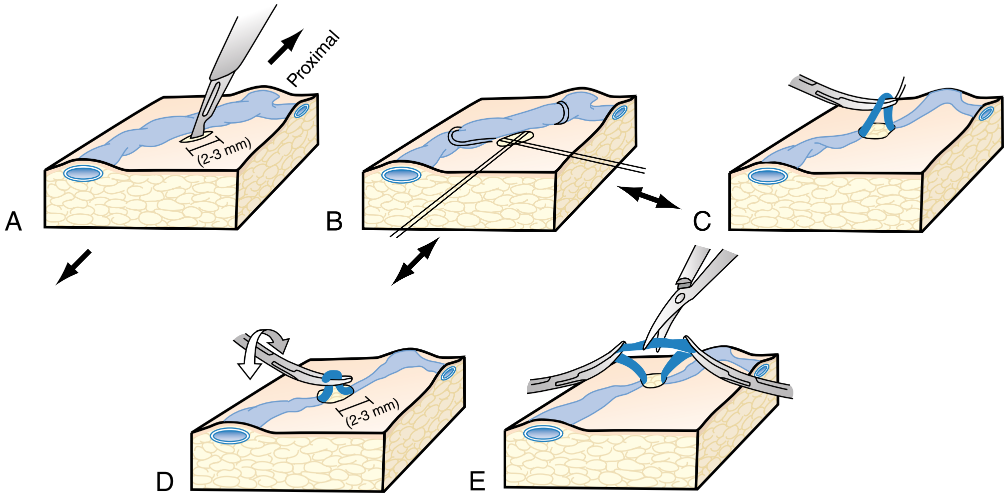

FIGURE 108.11 (A–E) Technique of ambulatory phlebectomy (otherwise known as *stab avulsions* of varicosities).

Stab Phlebectomy

Ambulatory phlebectomy is performed by the stab avulsion technique (Fig. 108.11). The patient's varicosities are marked after standing to allow optimal dilation and visualization of affected veins. Various anesthetic methods are used successfully, including local anesthesia with tumescence and IV sedation. First, 1-mm incisions are made along Langer skin lines, and the vein is retrieved with a hook. Continuous retraction of the vein segment affords maximal removal of the vein, and direct pressure is applied over the site after vein avulsion. Incisions are made at approximately 2-cm intervals. The extremity is wrapped with a layered compression dressing, and patients are instructed to ambulate on the day of surgery. The postoperative course is brief, and rarely do patients require more than acetaminophen or nonsteroidal antiinflammatory drugs for discomfort. Compression stockings are worn for 2 weeks after the procedure. Complications are unusual but include bleeding, infection, temporary or permanent paresthesia, and phlebitis from retained vein segments. There can be recurrence.

TriVex

Transilluminated powered phlebectomy (TriVex) is a modality that can be used to treat extensive secondary branch varicosities. The patient's varicosities are circumferentially marked preoperatively; in the operating room, 2-mm incisions are made at these boundary sites. These incisions permit placement of a transilluminator and resection device. The instruments are inserted through a subcutaneous plane, just deep to the varicosities. The transilluminator not only provides visualization of the veins but also administers tumescent anesthesia. The resector is a rotating blade that transects the veins and then removes them through a high-suction tubing system. The extremity is wrapped with a multilayer compression dressing, and the patient is discharged with instructions to ambulate hourly. The patient returns to the office for a dressing change within 48 hours and is usually changed to standard compression hose. Discomfort is minimal, and over-the-counter analgesia is sufficient. Complications are unusual but can include contained hematoma, bleeding, temporary or permanent paresthesia, and phlebitis.

Secondary Venous Insufficiency

Secondary venous insufficiency is usually caused by a deep venous thrombus. Clinical manifestations of secondary venous insufficiency usually present at a more advanced stage of disease with skin change or ulcerations. In addition, patients may describe venous claudication, or a bursting pain in the calf, that is classic for secondary venous insufficiency. Conservative treatment regimens are similar to those described in the preceding section for primary insufficiency; however, these patients may require a higher grade of compression for efficacy (30–40 mm Hg). Interventional treatment focuses on the superficial and deep systems. Diagnostic interrogation of the deep venous system must be more comprehensive in these patients to determine whether they are candidates for deep surgical or endovenous reconstruction.

Surgery for Deep Venous Insufficiency

While conservative therapy is being pursued or when ulcer healing is achieved, appropriate diagnostic studies generally reveal patterns of venous reflux or segments of venous occlusion so that specific therapy can be prescribed for the individual limb being evaluated. Imaging by duplex ultrasound suffices for the detection of reflux if the examination is carried out while the patient is standing. Such noninvasive imaging may prove the only testing necessary beyond the handheld, continuous-wave Doppler instrument if superficial venous ablation is contemplated.

Surprisingly, superficial reflux may be the only abnormality present in advanced chronic venous stasis. Correction goes a long way toward permanent relief of chronic venous dysfunction and its cutaneous effects. A significant proportion of patients with venous ulceration have normal function in the deep veins, and surgical treatment is a useful option that can definitively address the hemodynamic derangements. Maintaining that all venous ulcers are surgically incurable is not reasonable when data suggest that superficial vein surgery holds the potential for ameliorating venous hypertension. A randomized controlled trial comparing compression therapy and surgery for superficial reflux versus conservative management alone has revealed significant improvement in patients who had been treated by the surgical component.[17] Early success in patients with CVI, superficial valvular incompetence, and venous ulceration has been obtained with endovenous radiofrequency and laser therapies.

In 1938, Linton emphasized the importance of perforating veins, and their direct surgical interruption was advocated.[20,21] This has fallen into disfavor because of a high incidence of postoperative wound-healing complications. In recent years, as evolution in endovenous ablation continued, a radiofrequency stylet was developed that can be used for thermal ablation of the perforator veins in an outpatient setting that foregoes any need for incision and therefore avoids any possibility of wound-healing complications. The stylet is attached to needle and radiofrequency heating element. Using ultrasound guidance, the needle is introduced into the refluxing perforator vein, usually in the longitudinal view. The bioimpedance is tracked as the needle traverses the subcutaneous tissue because there is a change in bioimpedance as the needle is placed within the vein. When its location is confirmed, radiofrequency energy is transmitted, similar to RFA of axial veins. Studies have shown that RFA of perforator veins that are directly under ulcer beds has promising results in wound healing. UGS can also be used as an effective alternative in treating refluxing perforator veins in patients with venous ulcerations.

Chronic Venous Insufficiency

As the limbs of patients with severe CVI were studied accurately, the term PTS gave way to the term *CVI;* a link to platelet and monocyte aggregates in the circulation reflected the leukocytic infiltrate of the ankle skin, with its lipodermatosclerosis and healed and open ulcerations.[22] Data regarding leukocytes in CVI accumulated and were consistent, showing that the activation of leukocytes sequestered in the cutaneous microcirculation during venous stasis was important to the development of the skin changes of CVI. This is reflected in the finding of adhesion markers between leukocytes and endothelial cells and increased production of leukocyte degranulation enzymes and oxygen free radicals. Nevertheless, experimental evidence was still required for decisive proof of the leukocyte hypothesis.

CVI is a common condition with significant clinical sequelae. During the past two decades, the minimally invasive endovenous management of CVI and varicose veins has progressed remarkably and caused a rapid shift of treatment for these patients from the operating room to the outpatient office setting. Developing an understanding and appreciation of the pathophysiology behind the disorder allows the physician to appropriately diagnose and treat CVI with techniques that are both acceptable to the patient and generate successful outcomes.

DEEP VENOUS THROMBOSIS

Lower Extremity Deep Venous Thrombosis

Acute DVT is a major cause of morbidity and mortality in the hospitalized patient, particularly in the surgical patient. The triad of venous stasis, endothelial injury, and hypercoagulable state, first posited by Virchow in 1856, has held true more than a century and a half later. Acute DVT poses several risks and has significant morbid consequences. The thrombotic process initiated in a venous segment, in the absence of anticoagulation or in the presence of inadequate anticoagulation, can propagate to involve more proximal segments of the deep venous system, thus resulting in edema, pain, and immobility. The most dreaded sequela to acute DVT is that of PE, a condition of potentially lethal consequence. The late consequence of DVT, particularly of the iliofemoral veins, can be CVI and, ultimately, PTS as a result of valvular dysfunction in the presence of luminal obstruction.

Chronic venous thrombosis differs from acute DVT in that the thrombus has been present for greater than 4 weeks. Symptoms can be similar to acute DVT but may also present similar to PTS. The thrombus starts to scar into the vessel wall. The patient's ultrasound findings are the main differentiation between acute and chronic DVT (see Table 108.1). Understanding the pathophysiology, standardizing protocols to prevent or reduce DVT, and instituting optimal treatment promptly are critical to reducing the incidence and morbidity of this unfortunately common condition.

Causes

Virchow's triad of stasis, hypercoagulable state, and endothelial injury is present in most surgical patients. It is also clear that increasing age places a patient at greater risk, with those older than 65 years representing a higher-risk population. In addition, many epidemiologic studies have reviewed additional factors that place patients at risk for the development of DVT, including malignant disease, increased body mass index, increasing age (especially patients >60 years of age), pregnancy, oral contraceptive use, prolonged immobilization, surgery, trauma, tobacco use, prior DVT, IVC filter placement, inflammatory bowel disease, and heart failure.[23]

Stasis

Labeled fibrinogen studies in patients and autopsy studies have demonstrated convincingly that the soleal sinuses are the most common sites of initiation of venous thrombosis. The stasis may contribute to the endothelial cellular layer contacting activated platelets and procoagulant factors, thereby leading to DVT. Stasis, in and of itself, has never been shown to be a causative factor for DVT. External compression can also be a contributing factor to stasis within a vein as a result of tumors or conditions such as May-Thurner syndrome or aneurysm of the iliac artery.

Hypercoagulable States

Our knowledge of hypercoagulable conditions continues to improve, but it is still in its early stages. The standard array of conditions screened for in searching for a hypercoagulable state is listed in Box 108.1. If any of these conditions is identified, a treatment regimen of anticoagulation is instituted for life, unless specific contraindications exist. It is generally appreciated that the postoperative patient, after major surgery, is predisposed to the formation of DVT. After major operations, large amounts of tissue factor may be released into the bloodstream from damaged tissues. Tissue factor is a potent procoagulant expressed on the leukocyte cell surface and in a soluble form in the bloodstream. Increases in platelet count, adhesiveness, changes in coagulation cascade, and endogenous fibrinolytic activity result from physiologic stress, such as major operation or trauma, and have been associated with an increased risk for thrombosis.

BOX 108.1 Hypercoagulable States

- Factor V Leiden mutation
- Prothrombin gene mutation
- Protein C deficiency
- Protein S deficiency
- Antithrombin III deficiency
- Homocysteinemia
- Antiphospholipid syndrome
- Lupus antibody
- Anticardiolipin antibody
- COVID-19 infection

Endothelial Injury

It has been clearly established that venous thrombosis occurs in veins that are distant from the site of operation; for example, it is well known that patients undergoing total hip replacement frequently develop contralateral lower extremity DVT.

In a series of experiments, animal models of abdominal and total hip operations were used to study the possibility of venous endothelial damage distant from the operative site. In these studies, jugular veins were excised after the animals were perfusion fixed. These experiments demonstrated that endothelial damage occurred after abdominal operations and was more severe after hip operations. There were multiple microtears noted within the valve cusps that resulted in exposure of the subendothelial matrix. The exact mechanisms whereby this injury at a distant site occurs and which mediators, cellular or humoral, are responsible are not clearly understood, but that the injury occurs is evident from these and other studies.

Complications

There are short- and long-term complications and sequela of DVT. This is an overview of complications associated with DVT.

Pulmonary Embolism

The most dreaded and potentially lethal complication of DVT is PE, which occurs when untreated distal thrombus travels into the pulmonary arteries and causes an occlusion. The symptoms of PE, ranging from dyspnea to chest pain and hypoxia, are nonspecific and require a high index of suspicion. These occlusions can become severe enough to cause pulmonary hypertension and, eventually, acute right ventricular heart strain and failure. If the patients with PE survive, they are at risk of chronic pulmonary hypertension. More detailed information on this condition is provided in Chapter 114.

Phlegmasia Alba/Cerulea Dolens

Phlegmasia alba and cerulea dolens occur in the setting of acute extensive DVT and are characterized by marked swelling, pain, and blanching (Alba) or cyanosis (Cerulea) of the extremity. The swelling becomes so severe that it causes an acute limb ischemia presentation. This is a rare occurrence, but it almost always affects the lower extremity. Patients will have acute iliofemoral DVT and symptoms of advanced disease in addition to swelling, pain, and discoloration; motor or sensory loss; and pulselessness as a late finding. Most often, patients receive an urgent surgical intervention to decrease the thrombus burden as well as fasciotomies for compartment syndrome. These interventions are discussed in the Surgical Management section.

Postthrombotic Syndrome

PTS is a common and unfortunate manifestation of DVT. It occurs in 20% to 50% of patients after a documented episode of DVT. The clinical presentation includes chronic edema, pain, and venous claudication. Venous ulcerations can occur. Risk factors for the development of PTS include persistent leg symptoms for months after the acute episode of DVT, an anatomically extensive DVT involving the iliofemoral system, recurrent ipsilateral DVTs, and a prolonged state of subtherapeutic anticoagulation for DVT. Unfortunately, treatment remains supportive, and compression therapy, elevation, and ambulation remain the mainstay of treatment for PTS.

Diagnostic Considerations

Incidence

Venous thromboembolism (VTE), which includes DVT and PE, affects about 900,000 people each year in the United States. About one-quarter of patients with VTE have sudden death without any prior symptoms. The incidence increases with increasing age, with an incidence of 0.5%/100,000 at 80 years of age. More than two-thirds of these patients have DVT alone, and the rest have evidence of PE. The recurrence rate with anticoagulation has been noted to be 6% to 7% in the ensuing 6 months. COVID-19 has become the newest addition to the etiologies for DVT. Research is ongoing, but studies suggest patients remain at increased risk for DVT up to 1 year after infection.[24]

In the United States, PE causes 60,000 to 100,000 deaths annually. A 28-day case-fatality rate of 9.4% after first-time DVT and a rate of 15.1% after first-time pulmonary thromboembolism have been observed. Aside from PE, secondary CVI (resulting from DVT) is significant in terms of cost, morbidity, and lifestyle limitations.[25] If the consequences of DVT in terms of PE and CVI are to be prevented, the prevention, diagnosis, and treatment of DVT must be optimized.

Clinical Diagnosis

The diagnosis of acute DVT requires a high index of suspicion. Most physicians are familiar with Homan sign, which refers to pain in the calf on dorsiflexion of the foot. Although the absence of this sign is not a reliable indicator of the absence of venous thrombus, the presence of Homan sign should prompt one to attempt to confirm the diagnosis. The extent of venous thrombosis in the lower extremity is an important factor in the manifestation of symptoms. For example, most calf thrombi may be asymptomatic unless there is proximal propagation. This is one reason that radiolabeled fibrinogen testing demonstrates a higher incidence of DVT than studies using imaging modalities. Only 40% of patients with venous thrombosis have any clinical manifestations of the condition.

Major venous thrombosis involving the iliofemoral venous system results in a massively swollen leg, with pitting edema (Fig. 108.12), pain, and blanching, a condition known as *phlegmasia alba dolens.* With further progression of disease, there may be such massive edema that arterial inflow can be compromised. This condition results in a painful blue leg, a condition called *phlegmasia cerulea dolens,* as mentioned earlier. With this evolution of the condition, venous gangrene can develop unless flow is restored.

Imaging Studies and Laboratory Tests

Duplex Ultrasound

The gold standard for the diagnosis of DVT is duplex ultrasound, a modality that combines Doppler ultrasound and color flow imaging. The advantage of this test is that it is noninvasive, comprehensive, and without any risk of reaction to contrast angiography. Doppler ultrasound is based on the principle of the impairment of an accelerated flow signal caused by an intraluminal thrombus. A detailed interrogation begins at the calf with imaging of the tibial veins and then proximally over the popliteal and femoral veins. A properly done examination evaluates flow with distal compression, which results in augmentation of flow, and with proximal compression, which should interrupt flow. If any segment of the venous system being examined fails to demonstrate augmentation on compression, venous thrombosis is suspected.

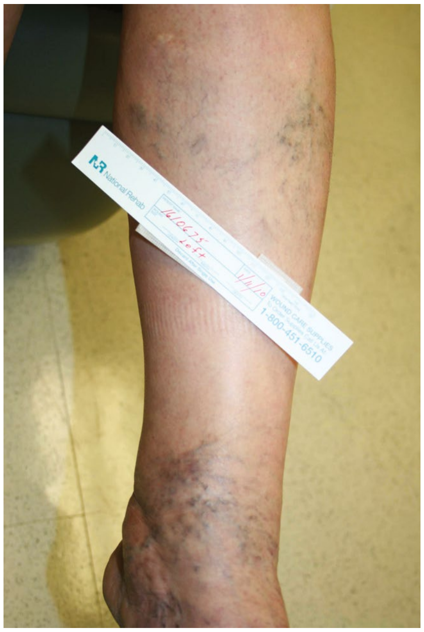

FIGURE 108.12 Edema. Note the loss of ankle definition.

Real-time B-mode ultrasonography with color flow imaging has improved the sensitivity and specificity of ultrasound scanning. With color flow duplex imaging, blood flow can be imaged in the presence of a partially occluding thrombus. The probe is also used to compress the vein. A normal vein is easily compressed, whereas in the presence of a thrombus, there is resistance to compression. In addition, the chronicity of the thrombus can be evaluated on the basis of its imaging characteristics, namely, increased echogenicity and heterogeneity.

Duplex imaging is significantly more sensitive than indirect physiologic testing. There are many advantages associated with duplex ultrasound: noninvasiveness, portability, and no need for a contrast agent. However, there are significant disadvantages as well; these include operator-dependent variability of skill, body habitus, and suboptimal visualization in regions such as the lower pelvis.

Venography

Injection of contrast material into the venous system has been long considered the most accurate method of confirming DVT and its location. It is the most sensitive and specific of all methods. However, it is an invasive test. The superficial venous system has to be occluded with a tourniquet, and the veins in the foot are injected for visualization of the deep venous system. Potential complications include risks of IV administration of contrast material and bleeding complications at the access sites. As a result, this technique has been replaced by less invasive modalities. Recently, the additional use of intravascular ultrasound (IVUS) has become more popular. This method provides a 360-degree two-dimensional gray-scale ultrasound image of lumen and vessel wall structures.[26]

Fibrin and Fibrinogen Assays

Fibrin and fibrinogen levels can be determined by measuring the degradation of intravascular fibrin. The D-dimer test measures cross-linked degradation products, which is a surrogate of plasmin's activity on fibrin. In combination with clinical evaluation and assessment, the sensitivity exceeds 90% to 95%. The negative predictive value is 99.3% for proximal evaluation and 98.6% for distal evaluation. In the postoperative patient, D-dimer is causally elevated because of surgery, and as such, a positive result of the D-dimer assay for evaluating for DVT is not useful. However, a negative D-dimer test result in patients with suspected DVT has a high negative predictive value, ranging from 97% to 99%.[27]

Computed Tomographic Venography

CTV has been shown to be a fast, high-spatial-resolution technique that can be used when looking for extension of thrombus or any other anatomic anomalies or compression that could be contributing to the etiology of the DVT, especially in the abdomen when looking at the iliac veins and IVC. The negatives include radiation exposure, complications associated with contrast material, more invasiveness compared with duplex because of the use of IV contrast material, and inaccuracy of visualization in the lower extremities as a result of dilution of contrast material.[28]

Magnetic Resonance Venography

With major advances in imaging technology, MRV has shown benefits in imaging for proximal venous disease. The cost and the issue of patient tolerance because of claustrophobia limit its widespread application, but this has been changing. It is a useful test for imaging the iliac veins and IVC, an area where the use of duplex ultrasound is limited. MRV is less invasive than conventional venography and is able to directly visualize the thrombus.

Impedance Plethysmography

Impedance plethysmography measures the change in venous capacitance and rate of emptying of the venous volume on temporary occlusion and release of the occlusion of the venous system. A cuff is inflated around the upper thigh until the electrical signal has plateaued. When the cuff is deflated, there is usually rapid outflow and reduction of volume. With a venous thrombosis, one notes a prolongation of the outflow wave. It is not useful clinically for the detection of calf venous thrombosis or in patients with prior venous thrombosis.

Prophylaxis

The patient who has undergone major abdominal or orthopedic surgery, has sustained major trauma, or has prolonged immobility (>3 days) represents an elevated risk for the development of VTE. The specific risk factor analysis and epidemiologic studies detailing the causes of VTE are beyond the scope of this chapter. The reader is referred to a more extensive analysis of this problem.[23] The methods of prophylaxis can be mechanical or pharmacologic.

Mechanical Prophylaxis

The simplest method is for the patient to walk. Activation of the calf pump mechanism is an effective means of prophylaxis, as evidenced by the fact that few active people without underlying risk factors develop venous thrombosis. A patient who is expected to be up and walking within 24 to 48 hours is at low risk for development of venous thrombosis. The practice of having a patient out of bed and into a chair is one of the most thrombogenic positions that could be ordered for a patient. Sitting in a chair, with the legs in a dependent position, causes venous pooling, which, in the postoperative milieu, could easily be a predisposing factor for the development of thromboembolism.

The most common method of surgical prophylaxis has traditionally revolved around compression stockings and SCDs, which periodically compress the calves and essentially replicate the calf bellows mechanism. This has clearly reduced the incidence of VTE in the surgical patient. The most likely mechanism for the efficacy of this device is prevention of venous stasis. Some studies have suggested that fibrinolytic activity is systemically enhanced by an SCD. However, this has not been definitively established because a considerable number of studies have demonstrated no enhancement of fibrinolytic activity, and SCDs are sometimes poorly tolerated by patients.[29]

Pharmacologic Prophylaxis

In the hospitalized patient, the most common form of thromboprophylaxis is fractionated low-molecular-weight heparin (LMWH) and unfractionated low-dose heparin (UFH). Various studies have revealed the efficacy of LMWH for the prophylaxis and treatment of VTE.[30–32] LMWH inhibits factor Xa and IIa activity, with the ratio of anti–factor Xa to anti–factor IIa activity ranging from 1:1 to 4:1. LMWH has a longer plasma half-life and significantly higher bioavailability. The consistent bioavailability and clearance of LMWH do not require monitoring of factor Xa levels, which facilitates use by the patient. Dosing is merely based on the patient's weight. There is a more predictable anticoagulant response than with UFH. No laboratory monitoring is necessary because the partial thromboplastin time (PTT) is unaffected. However, anti–factor Xa levels have been used to monitor its efficacy on a daily basis, and dosing can be adjusted to achieve a therapeutic level.[33]

Various analyses, including a major meta-analysis,[30] have shown that LMWH results in equivalent if not better efficacy than UFH, with significantly fewer complications, such as a lower incidence of heparin-induced thrombocytopenia and a lower likelihood of osteoporosis. It was first thought that LMWH results in less bleeding than unfractionated heparin, but no clinical observations have confirmed this. This property may be more a function of dose than an intrinsic drug action. UFH remains safer for patients with renal impairment because of the higher risk of bleeding events.[34] The dosage traditionally used was 5000 units of UFH every 12 hours. However, analyses of trials comparing placebo versus fixed-dose heparin have shown that the stated dose of 5000 units subcutaneously every 12 hours is no more effective than placebo.[32] When subcutaneous heparin is used on a dosing regimen of every 8 hours rather than every 12 hours, there is a reduction in the development of VTE.

Comparison of LMWH with mechanical prophylaxis has demonstrated the superiority of LMWH for reduction of the development of venous thromboembolic disease.[31,34] Prospective trials evaluating LMWH in head-injured and trauma patients have also proven the safety of LMWH, with no increase in intracranial bleeding or major bleeding at other sites.[35] In addition, LMWH shows a significant reduction in the development of VTE compared with other methods. Thus, LMWH is considered the optimal method of prophylaxis for moderate- and high-risk patients without any contraindications.

VTE is a common cause of perioperative morbidity and mortality. The CHEST guideline separates patients' risk of VTE based on their risk stratification.[36] In patients with very low risk for VTE ($<0.5\%$), the guideline recommends early ambulation without need for pharmacologic or mechanical prophylaxis. For patients at low risk of VTE ($\sim 1.5\%$), mechanical prophylaxis is recommended over chemical prophylaxis or a combination of both. Moderate-risk VTE patients ($\sim 3\%$) who are undergoing surgery are recommended chemical prophylaxis, including LMWH or UFH. However, only mechanical prophylaxis is recommended if the patient has a high risk of bleeding. For patients with a high risk for VTE ($\sim 6\%$) who are not at high risk of bleeding, pharmacologic prophylaxis with LMWH or UFH, in combination with mechanical prophylaxis, is recommended. Although the risk of VTE is present for several weeks after surgery, there are no clear data indicating benefit of extended pharmacologic prophylaxis, except in patients with a history of abdominal cancer surgery, who showed fewer VTE events in the 4-week prophylaxis group compared with the 1-week group. Therefore, the guideline recommends extended duration of pharmacologic prophylaxis in patients undergoing abdominal or pelvic surgery for cancer.[36]

Treatment

Acute Deep Vein Thrombosis Treatment

Anticoagulation. After a diagnosis of acute DVT has been made, a treatment plan must be instituted immediately. Complications of DVT include PE via proximal propagation of thrombus in up to one-third of hospitalized patients and chronic PTS, as mentioned earlier. In addition, untreated lower extremity DVT carries a 30% recurrence rate.

Any venous thrombosis involving the femoropopliteal system is treated with full anticoagulation. Traditionally, the treatment of DVT has centered around heparin treatment to maintain the PTT at 60 to 80 seconds, followed by warfarin therapy to obtain an international normalized ratio (INR) of 2.5 to 3.0. If unfractionated heparin is used, it is important to use a nomogram-based dosing therapy. The incidence of recurrent VTE increases if the time to therapeutic anticoagulation is prolonged. Therefore, it is important to reach therapeutic levels within 24 hours. An initial bolus of 80 units/kg or 5000 units IV bolus is administered, followed by 18 units/kg/h. The rate is dependent on a target PTT corresponding to an anti–factor Xa level of 0.3 to 0.7 unit/mL.[32] The PTT needs to be checked 6 hours after any change in heparin dosing. If warfarin is the long-term drug of choice, warfarin is started on the same day. The INR goal for therapeutic warfarin in the case of DVT is 2 to 3. If warfarin is initiated without heparin, the risk for a transient hypercoagulable state exists because protein C and protein S levels fall before the other vitamin K–dependent factors are depleted. With the advent of LMWH, it is no longer necessary to admit the patient for IV heparin therapy. It is now accepted practice to administer LMWH on an outpatient basis as a bridge to warfarin therapy, which is also monitored on an outpatient basis.

Recently, direct oral anticoagulants (DOACs) or novel oral anticoagulants (NOACs), which include direct thrombin inhibitor (dabigatran) and factor Xa inhibitors (rivaroxaban, apixaban, and edoxaban), have become a more attractive oral anticoagulant alternative to warfarin. Recent studies suggested that DOAC treatment, compared with warfarin, is associated with a lower risk of recurrent VTE and a lower risk of bleeding events.[37] DOACs also do not require a transitional period for initiation or outpatient INR monitoring.

The recommended duration of anticoagulant therapy is 3 to 6 months for the first DVT. The recurrence rate is the same with 3 versus 6 months. However, most practitioners will recommend 3 months of anticoagulation if there is a known reversible cause for the DVT, such as an injury, and 6 months if there is no known cause for DVT. If the patient has a known hypercoagulable state or has recurrent episodes of DVT, lifetime anticoagulation is required in the absence of contraindications. Repeat imaging after the course of treatment to establish a new baseline or to evaluate for change in the thrombus burden is physician dependent.

Warfarin is teratogenic, and DOACs are not recommended during pregnancy. In the case of the pregnant patient with venous thrombosis, LMWH is the treatment of choice; this is continued through delivery and can be continued postpartum, as indicated. Patients with a known history of cancer are typically treated with therapeutic LMWH because there have been efficacy studies showing superiority compared with warfarin. DOACs can also be prescribed for this population because DOACs were found to be noninferior to LMWH in a recent study for up to 6 months after diagnosis.[37]

Surgical management

Inferior vena cava filter. Adequate anticoagulation is usually effective for stabilizing venous thrombosis, but if a patient has contraindications to treatment with anticoagulation or if a patient develops propagating thrombus or PE in the presence of adequate anticoagulation, a vena cava filter is indicated. The general indications for a vena cava filter are listed in Box 108.2. Modern filters are placed percutaneously over a guidewire and are retrievable. The majority of IVC filters are placed infrarenal. In rare circumstances, such as in pregnancy, IVC filters are placed suprarenal. There are also superior vena cava filters for prevention of upper extremity DVT propagation.

Device-related complications are wound hematoma, migration of the device into the pulmonary artery, and caval occlusion caused by trapping of a large embolus. In the last situation, the dramatic hypotension that accompanies acute caval occlusion can be mistaken for a massive PE. The distinction between the hypovolemia of caval occlusion and the right-sided heart failure from PE can be made by measuring filling pressures of the right side of the heart. The treatment of caval occlusion is volume resuscitation. Although they are generally safe, IVC filters are not without risk and significant morbidity. Therefore, permanent placement of a caval filter is not generally recommended. Retrievable filters are mainly in use and are removed as soon as the patient has no contraindications to anticoagulation or months later. Complications with retained filters have been reported, including migration; penetration of legs into structures around the IVC, including the small intestine, aorta, and spine; and infection. For these reasons, recent authors recommend informing all patients with IVC filters that they must return for evaluation of the need for ongoing filtration and removal of filters when no contraindication to removal is present.[38,39]

Catheter-directed thrombolysis and percutaneous thrombectomy. The advent of thrombolysis and percutaneous thrombectomy has resulted in increased interest in percutaneous interventions for DVT. The purported benefit is preservation of valve function, with a subsequently lesser chance for development of PTS. In the Acute Venous Thrombosis: Thrombus Removal With Adjunctive Catheter Directed Thrombolysis (ATTRACT) trial, which compared the outcomes of patients with DVT who underwent catheter-directed thrombolysis (CDT) to standard therapy, there was no significant difference in the percentage of patients who developed PTS. However, CDT reduced the severity of PTS and decreased the severity of leg pain and swelling within the first month after treatment, but it increased major bleeding within 10 days of treatment compared with standard therapy alone. It is concluded that selective use to reduce PTS severity may be justified in patients who have a higher baseline risk for PTS. Quality-of-life improvement from baseline did not differ between the groups at 24 months. Based on the result of the ATTRACT trial, CDT may be recommended in patients with a more proximal, iliofemoral involvement and moderate to severe symptoms.[40]

Lately, percutaneous thrombectomy has become a more popular treatment option for percutaneous thrombolysis. With this procedure, the surgeon uses a percutaneous thrombectomy device via suction or mechanically to remove thrombus directly. The benefits of this procedure include decreased bleeding risk as well as immediate relief of thrombus burden. If a surgical option is pursued, treatment with anticoagulation is still recommended.

Open surgical venous thrombectomy. In the present day, open venous thrombectomy is reserved for patients who have phlegmasia with acute limb ischemia or have failed percutaneous intervention. This procedure is done by open cutdown to the vein and the use of Fogarty balloon catheters to extract thrombus. Extra precautions should be taken with proximal lesions because thrombus can dislodge and travel to the lungs. Temporary filters during the procedure can be placed in the IVC for prevention. After the thrombus has successfully been removed, traditionally, an arteriovenous fistula is surgically created to theoretically keep the vein patent.

BOX 108.2 Indications for an Inferior Vena Cava Filter

- Recurrent thromboembolism despite adequate anticoagulation
- Acute deep venous thrombosis in a patient with contraindications to anticoagulation
- Complications of anticoagulation
- Propagating iliofemoral venous thrombus on anticoagulation
- Prophylactic placement in high-risk trauma patients (orthopedic, spinal cord patients) who have short-term-duration contraindication to prophylactic anticoagulation

Chronic Deep Vein Thrombosis Treatment

The chronic thrombus is composed of mainly collagen and little fibrin. Therefore, thrombolytics are of very little use.

Conservative treatment. The mainstay of treatment for chronic DVT is conservative therapy. Recommendations for symptoms are compression and elevation. Patients sometimes develop ulcerations as a result of dysfunction of the valves and treatment, which is discussed in detail earlier in the Deep Venous Insufficiency section.

Surgical treatment. Chronic proximal venous occlusion of the iliofemoral system is a challenging clinical problem. No treatment is necessary for finding asymptomatic chronic DVT. For symptomatic chronic DVT, the presentation is variable, and there is no reliable diagnostic modality to measure proximal iliofemoral venous stenosis and assess outflow obstruction accurately. The pathophysiologic mechanism is often a combination of primary and secondary venous insufficiency. Endovascular reconstruction removes the need for surgical bypass and has been used successfully. Recanalization of the occluded iliac vein is performed endovascularly. Balloon dilation of the lesion is then performed, and if needed, a stent is placed across the dilated segment. Excellent results have been achieved, thereby obviating an open surgical procedure. Endovascular iliac therapy has evolved to become first-line therapy for iliac occlusions.

Upper Extremity Deep Venous Thrombosis—Venous Thoracic Outlet Syndrome

Upper extremity DVT is much less common than its lower extremity counterpart, constituting only approximately 5% of all documented DVTs. Although not as common, it is a serious problem; PE occurs in up to one-third of all patients with an upper extremity DVT. *Upper extremity DVT* usually refers to thrombosis of the axillary or subclavian veins. The syndrome can be divided into two categories: primary idiopathic and secondary.

Primary causes include Paget-Schroetter syndrome and idiopathic upper extremity DVT. Patients with Paget-Schroetter syndrome develop effort thrombosis of the extremity caused by compression of the subclavian vein, the venous component of thoracic outlet syndrome. A classic presentation involves a young athlete who uses the upper extremity in a repetitive motion, such as swimming, which causes repetitive extrinsic compression of the subclavian vein. In these patients, anatomic anomalies such as a cervical rib or myofascial bands cause venous compression. Plain films are one of the first diagnostic tests used to confirm thoracic outlet syndrome. Treatment with initial thrombolysis/thrombectomy followed by thoracic outlet decompression (anterior and middle scalene resection, first rib resection) with possible balloon angioplasty, stenting, or surgical reconstruction of the axillary and subclavian veins is the standard of care.

Idiopathic upper extremity DVT is sometimes eventually attributed to an occult malignant neoplasm; therefore, a diagnosis of idiopathic upper extremity DVT warrants evaluation for an undetected malignant neoplasm. Secondary causes of upper extremity DVT are more common. These include an indwelling central venous catheter, pacemaker, thrombophilia, and malignant disease.

Classic findings on physical examination include unilateral swelling, pain, extremity discomfort, erythema, and a palpable cord. Diagnosis is confirmed by duplex ultrasonography. Because the clavicle obscures the midportion of the subclavian vein, venography or magnetic resonance venography may be required; these are second-line imaging modalities.

Treatment

Treatment of upper extremity DVT is essentially the same as that for lower extremity DVT, which involves anticoagulation therapy. Therapeutic dosing parameters are the same as for lower extremity DVT. Treatment should be for 3 months and consist of heparin or LMWH plus warfarin for at least 3 months or DOACs. Long-term complications of upper extremity DVT include recurrence and PTS. Thrombolysis has not been shown to decrease long-term manifestations from upper extremity DVT; thus, PTS is treated with extremity elevation and graduated elastic compression.[41,42]

SUPERFICIAL VENOUS THROMBOPHLEBITIS

SVT is a common disorder diagnosed in the hospital and outpatient setting. Cardinal signs of SVT are rubor, calor, dolor, and tumor, describing a linear, erythematous, tender, and swollen lesion along the course of a superficial vein. The condition is self-limiting in the majority of patients, and as result of the inflammatory reaction, the superficial vein becomes a palpable fibrotic cord. In hospitalized patients, SVT is usually caused by an indwelling catheter. In the clinic, patients with thrombophlebitis report common predisposing risk factors, such as recent surgery, recent childbirth, venous stasis, varicose veins, or IV drug use. Patients who deny any of these factors may be classified with idiopathic thrombophlebitis. In these cases, care must be taken to ensure that the patient does not harbor an occult hypercoagulable state or occult malignant disease. In 1876, Trousseau identified the phenomenon of migratory thrombophlebitis and malignant disease, particularly involving the tail of the pancreas. Mondor disease involves SVT of the superficial veins of the breast. Diagnosis of SVT can be easily made by physical examination of an erythematous palpable cord coursing along a superficial vein, usually located along the lower extremities. Duplex ultrasonography is recommended to confirm diagnosis and if there is suspicion of possible proximal propagation into the deep venous system. With this diagnosis of DVT, anticoagulation is indicated. If, however, thrombus abuts the SFJ, treatment of this more elusive condition is controversial. Some authors recommend serial ultrasound examinations, whereas others recommend anticoagulation; another alternative is operative ligation at the junction.

The initial treatment of localized noncomplicated thrombophlebitis involves conservative therapy, which consists of antiinflammatory medication and compression stockings. The recommended treatment of an SVT involving a ≥5-cm GSV segment is a midtreatment dose of LMWH (enoxaparin 60 mg daily subcutaneously) or fondaparinux (2.5 mg daily subcutaneously) for a 6-week period. A similar treatment is recommended if the thrombophlebitis ascends the GSV within 3 cm from the SFJ. Results from the Superficial Vein Thrombosis Treated for 45 Days With Rivaroxaban Versus Fondaparinux (SURPRISE) trial have shown noninferiority of rivaroxaban at the dosage of 10 mg daily compared with fondaparinux (2.5 mg daily subcutaneously) for 45 days in the treatment of SVT. When thrombophlebitis involves clusters of varicosities, particularly in the lower extremities, excision may be indicated. Selective removal of the entire vein along its course is indicated only in the rare case of suppurative septic thrombophlebitis after all other sources of sepsis have been excluded.

CONCLUSION

This is just a small proportion of the spectrum of venous diseases and disorders, which are widespread and diverse, providing surgeons who fully understand the unique physiology of veins a rewarding and rich field for patient care and future investigation.

  Upper Extremity Lymphedema

EMBRYOLOGY AND ANATOMY

The primordial lymphatic system is first seen during the sixth week of development in the form of lymph sacs located next to the jugular veins. During the eighth week, the cisterna chyli forms just dorsal to the aorta, and at the same time, two additional lymphatic sacs corresponding to the iliofemoral vascular pedicles begin forming. Communicating channels connecting the lymph sacs, which will become the thoracic duct, develop during the ninth week.

From this primordial lymphatic system sprout endothelial buds that grow with the venous system to form the peripheral lymphatic plexus (Fig. 109.1). Failure of one of the initial jugular lymphatic sacs to develop proper connections and drainage with the lymphatic system and, subsequently, the venous system may produce focal lymph cysts (cavernous lymphangiomas), also known as *cystic hygromas.*[1] Similarly, failure of embryologic remnants of lymphatic tissues to connect to efferent channels leads to the development of cystic lymphatic formations (simple capillary lymphangiomas) that, depending on their location, are classified as truncal, mesenteric, intestinal, and retroperitoneal lymphangiomas. Hypoplasia or failure of development of drainage channels connecting the lymphatic systems of extremities to the main primordial lymphatic system of the torso may result in primary lymphedema of the extremities.

Lymphangiogenesis appears to be regulated by the vascular endothelial growth factors C and D (VEGF-C, VEGF-D); their receptor, VEGFR-3; and their binding protein, neuropilin 2 (Nrp2). Consistent with these findings, Nrp2-deficient mice have lymphatic hypoplasia, and heterozygous inactivating mutation of VEGFR-3 is found in Chy mice, an animal model of primary lymphedema, which appears to be the underlying problem in patients with Milroy disease (congenital familial lymphedema).[2] A number of additional genes have recently been found to be related to lymphatic disorders.[3] The best studied at this point are the gene for the forkhead family transcription factor FOXC2 (responsible for the hereditary lymphedema-distichiasis syndrome) and the gene for the transcription factor SOX18 (related to recessive and dominant forms of hypotrichosis-lymphedema-telangiectasia). As more causal genes are identified, the possibility arises for a classification built on patient phenotypes for which the gene is known.[4] Receptor activity-modifying protein 1 (RAMP1) has also been identified as an important factor for lymphangiogenesis. RAMP1 knockout mice have greater amounts of surgery-associated lymphedema compared with controls. This is thought to occur from a lack of attenuation of proinflammatory macrophage recruitment in the RAMP1 knockout mice.[5]

FUNCTION AND STRUCTURE

The lymphatic system is composed of three elements: (1) the initial or terminal lymphatic capillaries, which absorb lymph; (2) the collecting vessels, which serve primarily as conduits for lymph transport; and (3) the lymph nodes, which are interposed in the pathway of the conducting vessels, filtering the lymph and serving a primary immunologic role.

The terminal lymphatics have special structural characteristics that allow entry not only of large macromolecules but even of cells and microbes. Their most important structural feature is a high porosity resulting from a very small number of tight junctions between endothelial cells, a limited and incomplete basement membrane, and anchoring filaments (4–10 nm) tethering the interstitial matrix to the endothelial cells. These filaments, once the turgor of the tissue increases, are able to pull on the endothelial cells and essentially introduce large gaps between them, which then allow very low-resistance influx of interstitial fluid and macromolecules in the lymphatic channels. The collecting vessels ascend alongside the primary blood vessels of the organ or limb, pass through the regional lymph nodes, and drain into the main lymph channels of the torso. These channels eventually empty

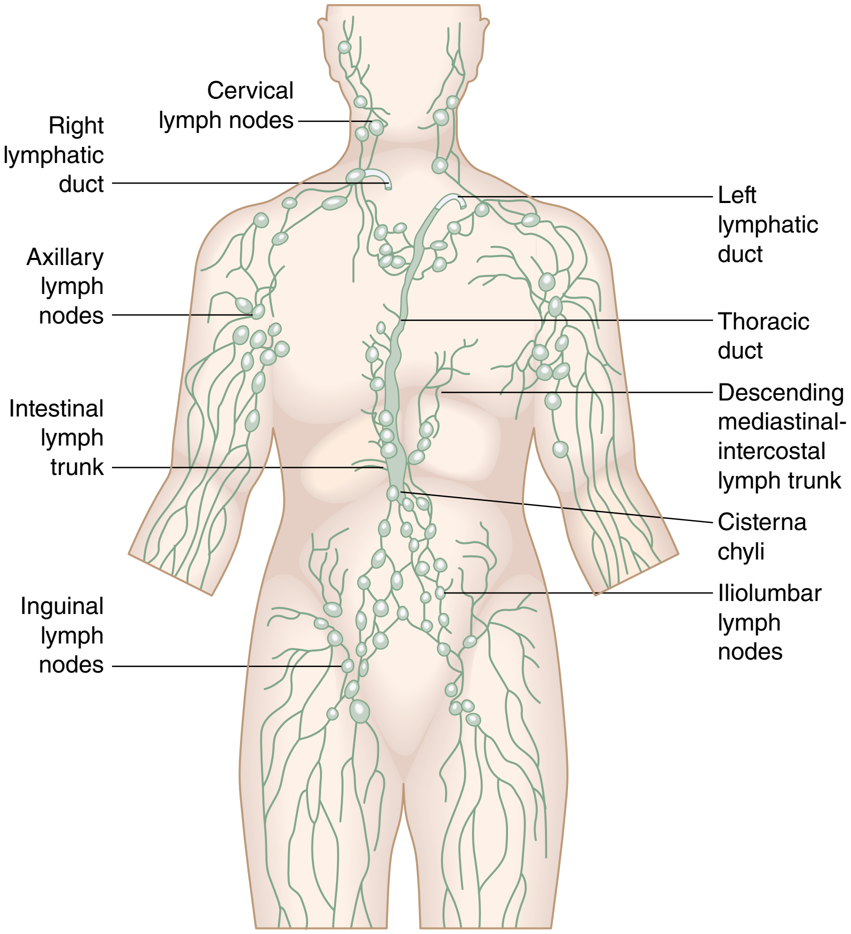

FIGURE 109.1 Major anatomic pathways and lymph node groups of the lymphatic system.

into the venous system through the thoracic duct. There are additional communications between the lymphatic and venous systems. These smaller lymphovenous shunts mostly occur at the level of lymph nodes and around major venous structures, such as the jugular, subclavian, and iliac veins. Several structures in the body contain no lymphatics. Specifically, lymphatics have not been found in the epidermis, cornea, central nervous system, cartilage, tendon, and muscle.

The lymphatic system has three main functions. First, tissue fluid and macromolecules that undergo ultrafiltration at the level of the arterial capillaries are reabsorbed and returned to the circulation through the lymphatic system. Every day, 50% to 100% of the intravascular proteins are filtered this way in the interstitial space. Normally, they then enter the terminal lymphatics and are transported through the collecting lymphatics back into the venous circulation. Second, antigens, immune cells, microbes, and mutant cells arriving in the interstitial space enter the lymphatic system and are presented to the lymph nodes, which represent the first line of the immune system. Last, at the level of the gastrointestinal tract, lymph vessels are responsible for the uptake and transport of most of the fat absorbed from the bowel. Recent data suggest that a relationship between fat and lymphatics may exist well beyond the gut alone. It appears that peripheral tissue lipid transport and homeostasis may be, in part, determined by lymphatic function, hence the increased fat deposition seen in lymphedema.[3,6]

In contrast to what happens with venous forward flow, lymph's centripetal transport occurs mainly through intrinsic contractility of the individual lymphatic vessels, which, in concert with competent valvular mechanisms, is effective in establishing constant forward flow of lymph. In addition to the intrinsic contractility, other factors, such as surrounding muscle activity, negative pressure secondary to breathing, and transmitted arterial pulsations, have a lesser role in the forward lymph flow. These secondary factors appear to become more important under conditions of lymph stasis and congestion of the lymphatic vessels.

PATHOPHYSIOLOGY AND STAGING

Lymphedema is the result of an inability of the existing lymphatic system to accommodate the protein and fluid entering the interstitial compartment at the tissue level.[7] Impaired lymphatic vasculature can be either aplastic, hypoplastic, or hyperplastic. All of these patterns can lead to clinical lymphedema. In aplasia and hypoplasia, an absent or diminished number of lymphatics is seen. In hyperplasia, the vessels are incompetent and tortuous. Hyperplasia is only a cause in 8% of patients with lymphedema.[8]

An international working group developed a clinical staging for lymphedema.[9] In the latent phase, excess fluid accumulates, and the lymphatics become fibrosed. In the *latent phase* (grade 0), there is no clinical evidence of edema. In the *first stage* of lymphedema (grade I), impaired lymphatic drainage results in protein-rich fluid accumulation in the interstitial compartment. Clinically, this is manifested as soft pitting edema. In the *second stage* of lymphedema (grade II), the clinical condition is further exacerbated by accumulation of fibroblasts, adipocytes, and perhaps most important, macrophages in the affected tissues, which culminates in a local inflammatory response. This results in important structural changes from the deposition of connective tissue and adipose elements at the skin and subcutaneous level. In the second stage of lymphedema (grade II), tissue edema is more pronounced, is nonpitting, and has a spongy consistency. Elevation does not reduce the edema, and skin fibrosis is more apparent. In the *third* and most advanced stage of lymphedema (grade III), the affected tissues sustain further injury as a result of both the local inflammatory response and recurrent infectious episodes that typically result from minimal subclinical breaks in the skin. Such repeated episodes injure the incompetent, remaining lymphatic channels, progressively worsening the underlying insufficiency of the lymphatic system. This eventually results in excessive subcutaneous fibrosis and scarring with associated severe skin changes characteristic of lymphostatic elephantiasis. Edema is irreversible at this stage.

DIFFERENTIAL DIAGNOSIS

In most patients with second- or third-stage lymphedema, the characteristic findings on physical examination can usually establish the diagnosis. The edematous limb has a firm and hardened consistency. There is a loss of the normal perimalleolar shape, resulting in a "tree trunk" pattern. The dorsum of the foot is characteristically swollen, resulting in the appearance of the "buffalo hump," and the toes become thick and squared, known as *Stemmer sign* (Fig. 109.2). In advanced lymphedema, the skin undergoes characteristic changes, such as lichenification, development of peau d'orange, and hyperkeratosis.[7] In addition, the patients give a history of recurrent episodes of cellulitis and lymphangitis after trivial trauma and frequently present with fungal infections affecting the forefoot and toes. Patients with isolated lymphedema usually do not have the hyperpigmentation or ulceration one typically sees in patients with chronic venous insufficiency. Lymphedema does not respond significantly to overnight elevation, whereas edema secondary to central organ failure or venous insufficiency does.

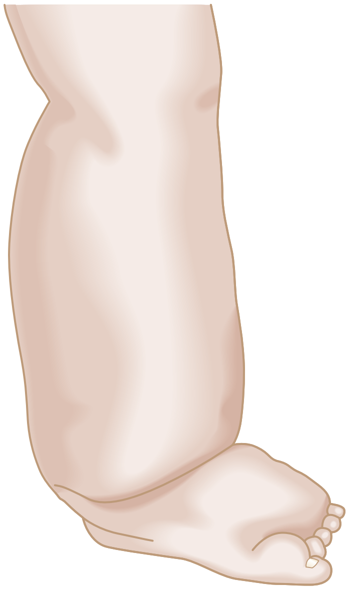

FIGURE 109.2 Lymphedema with characteristic loss of the normal perimalleolar shape, resulting in a "tree trunk" pattern. Dorsum of the foot is characteristically swollen, resulting in the appearance of the "buffalo hump."

The evaluation of a swollen extremity should start with a detailed history and physical examination. The most common causes of bilateral extremity edema are of systemic origin. The most common cause is cardiac failure, followed by renal failure.[10] Hypoproteinemia secondary to cirrhosis, nephrotic syndrome, and malnutrition can also produce bilateral lower extremity edema. Another important cause to consider with bilateral leg enlargement is lipedema. Lipedema is not true edema but rather excessive subcutaneous fat typically found in obese females. It is bilateral, nonpitting, and greatest at the ankle and legs, with characteristic sparing of the feet. There are no skin changes, and the enlargement is not affected by elevation. The history usually indicates that this has been a lifelong problem that "runs in the family."

Once the systemic causes of edema are excluded in the patient with unilateral extremity involvement, edema secondary to venous and lymphatic disease should be entertained. Venous disease is overwhelmingly the most common cause of unilateral leg edema. Leg edema secondary to venous disease is usually pitting and is greatest at the legs and ankles, with sparing of the feet. The edema responds promptly to overnight leg elevation and is controlled with regular compression. In the later stages, the skin is atrophic, with brawny pigmentation from hemosiderin deposition. Ulceration associated with venous insufficiency occurs above or posterior to and beneath the malleoli.

CLASSIFICATION

Lymphedema is generally classified as primary when there is no known cause and secondary when its cause is a known disease or disorder.[11] Primary lymphedema has generally been classified on the basis of the age at onset and presence of familial clustering. Primary lymphedema with onset before the first year of life is called *congenital lymphedema*. The familial version of congenital lymphedema is known as *Milroy disease* and is inherited as a dominant trait. Primary lymphedema with onset between the ages of 1 and 35 years is called *lymphedema praecox*. The familial version of lymphedema praecox is known as *Meige disease* and has an onset around puberty. Finally, primary lymphedema with onset after the age of 35 years is called *lymphedema tarda*. The primary lymphedemas are relatively uncommon, occurring in 1 out of every 10,000 individuals. The most common form of primary lymphedema is praecox, which accounts for approximately 80% of the patients. Congenital and tarda lymphedemas each account for 10%. Worldwide, the most common cause of secondary lymphedema is infestation of the lymph nodes by the parasite *Wuchereria bancrofti* in the disease state called *filariasis*. Generally, the lower extremities are affected; however, primary upper extremity lymphedema has been reported.

Acquired or secondary lymphedema is the most common cause of lymphedema. In the developed countries, the most common causes of secondary lymphedema involve resection or ablation of regional lymph nodes by surgery, radiation therapy, tumor invasion, direct trauma, or, less commonly, an infectious process. For patients undergoing treatment for breast cancer with axillary intervention, up to 30% of patients will describe clinically significant lymphedema of the arm.

DIAGNOSTIC TESTS

The diagnosis of lymphedema is relatively easy in the patient who presents in the second and third stages of the disease. It can, however, be a difficult diagnosis to make in the first stage, particularly when the edema is mild, pitting, and relieved with simple maneuvers such as elevation.[11,12] For patients with suspected secondary forms of lymphedema, computed tomography (CT) and magnetic resonance imaging (MRI) are valuable and indeed essential for exclusion of underlying oncologic disease states.[13] In patients with known lymph node excision and radiation treatment as the underlying problem of their lymphedema, additional diagnostic studies are rarely needed except as these studies relate to follow-up of an underlying malignant disease. For patients with edema of unknown cause and a suspicion for lymphedema, lymphoscintigraphy is the diagnostic test of choice. When lymphoscintigraphy confirms that lymphatic drainage is delayed, the diagnosis of primary lymphedema should never be made until neoplasia involving the regional and central lymphatic drainage of the limb has been excluded through CT or MRI. If a more detailed diagnostic interpretation of lymphatic channels is needed for operative planning, contrast lymphangiography may be considered.

Lymphoscintigraphy (or isotope lymphography) has emerged as the test of choice in patients with suspected lymphedema.[13,14] It cannot differentiate between primary and secondary lymphedemas; however, it has a sensitivity of 70% to 90% and a specificity of nearly 100% in differentiating lymphedema from other causes of limb swelling. The test assesses lymphatic function by quantitating the rate of clearance of a radiolabeled macromolecular tracer (Fig. 109.3). The advantages of the technique are that it is simple, safe, and reproducible, with small exposure to radioactivity (approximately 5 mCi). It involves the injection of a small amount of radioiodinated human albumin or technetium-99m–labeled sulfur colloid into the first interdigital space of the foot or hand. Migration of the radiotracer within the skin and subcutaneous lymphatics is easily monitored with a whole body gamma camera, thus producing clear images of the major lymphatic channels in the leg and measuring the amount of radioactivity at the inguinal nodes 30 and 60 minutes after injection of the radiolabeled substance in the feet. An uptake value that is less than 0.3% of the total injected dose at 30 minutes is diagnostic of lymphedema. The normal range of uptake is between 0.6% and 1.6%. In patients with edema secondary to venous disease, isotope clearance is usually abnormally rapid, resulting in more than 2% ilioinguinal uptake. Importantly, variation in the degree of edema involving the lower extremity does not appear to significantly change the rate of clearance of the isotope.

Direct contrast lymphangiography provides the finest details of the lymphatic anatomy.[15] However, it is an invasive study that involves exposure and cannulation of lymphatics at the dorsum of the forefoot, followed by slow injection of contrast medium (ethiodized oil). The procedure is tedious, the cannulation often necessitates aid of magnification optics (frequently an operating microscope is needed), and the dissection requires some form of anesthetic. After cannulation of a superficial lymph vessel, contrast material is slowly injected into the lymphatic system. A total of 7 to 10 mL of contrast material is ideal for lower extremity evaluation and 4 to 5 mL for upper extremity evaluation. Potential complications include damage of the visualized lymphatics, allergic reactions, and pulmonary embolism if the oil-based contrast agent enters the venous system through lymphovenous anastomoses. Lymphangiography in present surgical practice is used infrequently and solely reserved for the preoperative evaluation of selected patients who are candidates for direct operations on their lymphatic vessels.

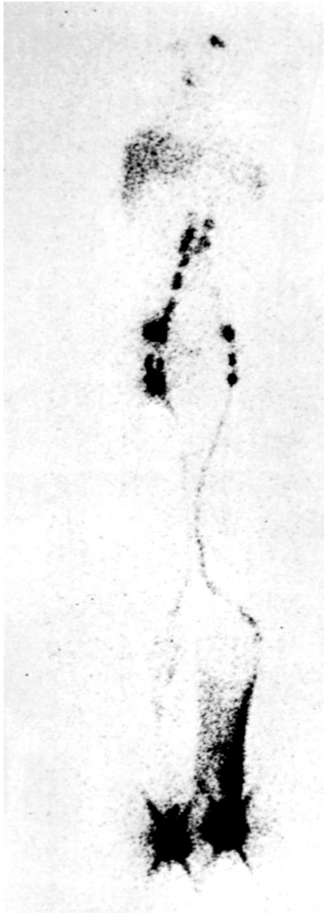

FIGURE 109.3 Lymphoscintigraphic pattern in primary lymphedema. Note area of dermal backflow on the *left* and diminished number of lymph nodes in the groin. (From Cambria RA, Gloviczki P, Naessens JM, et al. Noninvasive evaluation of the lymphatic system with lymphoscintigraphy: a prospective, semiquantitative analysis in 386 extremities. *J Vasc Surg*. 1993;18:773-782.)

New Diagnostic Tests

The field of lymphatic imaging is ever evolving, and we can expect that technologic advances, combined with the development of new contrast agents, will continue to improve diagnostic accuracy.[13] The most promising new test appears to be contrast magnetic resonance lymphangiography.[13,16] The test is performed after intracutaneous injection of gadobenate dimeglumine into the interdigital webs of the dorsal foot. Reported data suggest that the new test is capable of visualizing the anatomy and functional status of lymph flow transport of lymphatic vessels and lymph nodes of lymphedematous limbs in both primary and secondary lymphedema. Another new test that holds promise to detect early disease is bioimpedance spectroscopy. Flow of electrical current in a particular region of the body is inversely related to the amount of fluid in the tissue. With early lymphedema and increased interstitial fluid, impedance decreases. Although tested in small samples, sensitivity and specificity have been found to be 100%.[17]

Groups are looking at using machine learning and artificial intelligence to use CT for analysis of lymphedema and to potentially use this to screen patients.[18] For surgical planning, some providers are successfully using noncontrast magnetic resonance lymphangiography instead of conventional lymphangiography. This imaging can provide the necessary lymphatic imaging via a noninvasive means.[19]

THERAPY

Most patients with lymphedema can be treated with a combination of limb elevation, a high-quality compression garment, complex decongestive physical therapy, and compression pump therapy. We currently have no effective medications for the treatment of lymphedema. Operative treatment may be considered for patients with advanced complicated lymphedema for whom management with nonoperative means has failed.

General Therapeutic Measures

All patients with lymphedema should be educated in meticulous skin care and avoidance of injuries.[12,19] The patients should always be instructed to see their physicians early for signs of infections because these may progress rapidly to serious systemic infections. Infections should be aggressively and promptly treated with appropriate antibiotics directed at gram-positive cocci. Eczema at the level of the forefoot and toes requires treatment, and hydrocortisone-based creams may be considered. In addition, basic range-of-motion exercises for the extremities have been shown to be of value in the management of lymphedema in the long term. Finally, the patients should make every effort to maintain ideal body weight.

Elevation and Compression Garments

For lymphedema patients in all stages of disease, management with high-quality elastic garments is necessary at all times except when the legs are elevated above the heart.[20,21] The ideal compression garment is custom fitted and delivers pressures in the range of 30 to 60 mm Hg. Such garments may have the additional benefit of protecting the extremity from injuries, such as burns, lacerations, and insect bites. The patients should avoid standing for prolonged periods and should elevate their legs at night by supporting the foot of the bed on 15-cm blocks.

Complete Decongestive Physical Therapy

Complete decongestive physical therapy, a specialized massage technique for patients with lymphedema, is designed to stimulate the still-functioning lymph vessels, evacuate stagnant protein-rich fluid by breaking up subcutaneous deposits of fibrous tissue, and redirect lymph fluid to areas of the body where lymph flow is normal.[22] The technique is initiated on the normal contralateral side of the body, evacuating excessive fluid and preparing first the lymphatic zones of the nonaffected extremity, followed by the zones in the trunk quadrant adjacent to the affected limb, before attention is turned to the swollen extremity. The affected extremity is massaged in a segmental fashion, with the proximal zones being massaged first, proceeding to the distal limb. The technique is time consuming but effective in reducing the volume of the lymphedematous limbs.[22] After the massage session is complete, the extremity is wrapped with a low-stretch wrap, and then the limb is placed in the custom-fitted garment to maintain the decreased girth obtained with the massage therapy. This kind of therapy is appropriate for patients with all stages of lymphedema.

When the patient is first referred for complex decongestive physical therapy, the patient undergoes daily to weekly massage sessions for up to 8 to 12 weeks (initial or reductive stage). Limb elevation and elastic stockings are necessary adjuncts in this phase. After maximal volume reduction is achieved, the patient returns for maintenance massage treatments every 2 to 3 months while continuing to wear compression garments (maintenance phase). Without adherence to therapy, lymphatic fluid will reaccumulate. Lifelong maintenance is imperative to maintain reduction. Volume reduction is generally 60% to 70%, and compliant patients retain 90% of this reduction. A consensus panel with experts from the American Venous Forum, the American Vein and Lymphatic Society, and the Society for Vascular Medicine supports the use of manual lymphatic drainage, one component of complete decongestive therapy, for all lymphedema patients, even in the early stages of the disease.[23]

Compression Pump Therapy

Pneumatic compression pump therapy is another effective method of reducing the volume of the lymphedematous limb by a similar principle to massage therapy. The device consists of a sleeve containing several compartments. The lymphedematous limb is positioned inside the sleeve, and the compartments are serially inflated to milk the stagnant fluid out of the extremity.[24]

When a patient with advanced lymphedema is first referred for therapy, an initial approach with hospitalization for 3 or 4 days involving strict limb elevation, daily complex decongestive physical therapy, and compression pump treatments may be necessary to achieve optimal control of the lymphedema. It is particularly important that patients with cardiac or renal dysfunction be monitored for fluid overload. After this initial period of intensive therapy, the patients are fitted with high-quality compression garments to maintain the limb volume. Maintenance sessions are then prescribed for the patients on an as-needed basis.

Drug Therapy

Benzopyrones have attracted interest as potentially effective agents in the treatment of lymphedema. This class of medications, which includes coumarin (1,2-benzopyrone), is thought to reduce lymphedema through stimulation of proteolysis by tissue macrophages and stimulation of the peristalsis and pumping action of the collecting lymphatics. Benzopyrones have no anticoagulant activity. The first randomized, crossover trial of coumarin in patients with lymphedema of the arms and legs was reported in 1993.[25] The study concluded that coumarin was more effective than placebo in reducing not only volume but also other important parameters, including skin temperature, attacks of secondary acute inflammation, and discomfort of the lymphedematous extremities; skin turgor and suppleness were improved with coumarin. A second randomized, crossover trial was reported in 1999.[26] This study focused on effects of coumarin in females with secondary lymphedema after treatment of breast cancer. The trial investigators found that coumarin was not effective therapy for the specific group of females. Because of the disagreement between these two major trials, coumarins are not recommended for lymphedema treatment.

Diuretics may temporarily improve the appearance of the lymphedematous extremity with stage I disease, leading patients to request continuous therapy. However, other than producing temporary intravascular volume depletion, there is no long-term benefit because lymphedema fluid is not in the vascular space. Thus, diuretics have no role in the treatment of lymphedema at any stage.

Molecular Lymphangiogenesis

Fundamental discoveries in lymphatic development have pointed to the potential of exciting new treatments for lymphedema.

These molecular treatments are based on the activation of the VEGFR-3 pathway by administration of cognate ligands VEGF-C and VEGF-D using a variety of methods.[27] At this point, these treatments have been tested only in animal models, with promising results. Formal clinical trials are now needed to evaluate the therapeutic potential and possible untoward effects (including the possibility of stimulation of dormant tumor cells as a consequence of increased angiogenesis) of therapeutic lymphangiogenesis.[28]

Operative Treatment

Of patients with lymphedema, 95% can be managed nonoperatively. Surgical intervention may be considered for patients with stage II or stage III lymphedema who have severe functional impairment, recurrent episodes of lymphangitis, and severe pain despite optimal medical therapy. Two main categories of operations are available for the care of patients with lymphedema: reconstructive and excisional.

Reconstructive operations[29,30] should be considered for those patients with proximal (either primary or secondary) obstruction of the extremity lymphatic circulation with preserved, dilated lymphatics peripheral to the obstruction. In these patients, the residual dilated lymphatics can be anastomosed either to nearby veins or to transposed healthy lymphatic channels (usually mobilized or harvested from the healthy lower extremity) in an attempt to restore effective drainage of the lymphedematous extremity (Fig. 109.4). Some of the most common candidates for reconstructive procedures are patients with upper extremity lymphedema secondary to axillary lymphadenectomy or patients with leg lymphedema secondary to inguinal or pelvic lymphadenectomy. Treatment of selected lymphedema patients with lymphovenous anastomoses, lymphovenous bypass, or lymphaticolymphatic bypass has resulted in objective improvement in 30% to 80% of the patients, with an average initial reduction in the excess limb volume of 30% to 84%.[31–34]

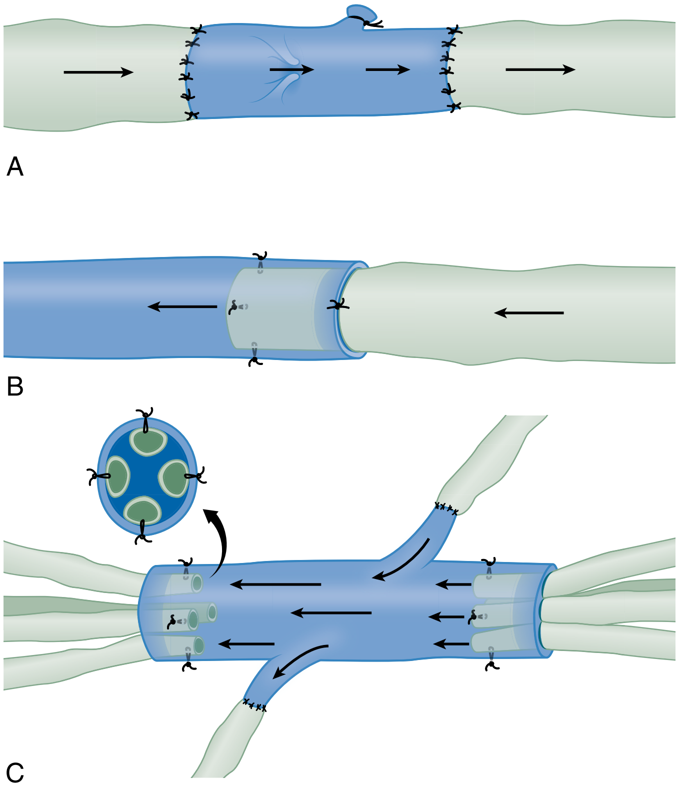

FIGURE 109.4 Lymphatic reconstruction techniques with a venous interposition graft (A), a lymphovenous anastomosis (B), and invagination of multiple lymphatics into a vein graft (C). (From Campisi C, Boccardo F, Tacchella M. Reconstructive microsurgery of lymph vessels: the personal method of lymphatic-venous-lymphatic [LVL] interpositioned grafted shunt. *Microsurgery.* 1995;16:161-166.)

A new surgical strategy involving lymph node transplantation has been used successfully, particularly for upper extremity lymphedema. This technique involves completing a gastroepiploic omental harvest, quantifying the number of lymph nodes in the flap, and performing a microvascular anastomosis in the extremity of interest. Debulking lipectomy was also performed in conjunction with this procedure. This technique has shown improvement in limb size and quality of life.[35]

Excisional operations are essentially the only viable option for patients without residual lymphatics of adequate size for reconstructive procedures. For patients with recalcitrant stage II and early stage III lymphedema in whom the edema is moderate and the skin is relatively healthy, an excisional procedure that removes a large segment of the lymphedematous subcutaneous tissues and overlying skin is the procedure of choice. This palliative procedure was introduced by Kontoleon in 1918 and was later popularized by Homan as "staged subcutaneous excision underneath flaps" (Fig. 109.5). The operative approach starts with a medial incision extending from the level of the medial malleolus through the calf into the midthigh.[36] Flaps about 1 to 2 cm thick are elevated anteriorly and posteriorly, and all subcutaneous tissue beneath the flaps, along with the underlying medial calf deep fascia, is removed with the redundant skin. The sural nerve is preserved. After the first-stage procedure is completed and if additional lymphedematous tissue removal is necessary, a second operation is performed, usually 3 to 6 months later. The second-stage operation is performed by similar techniques through an incision on the lateral aspect of the limb. In a recent long-term follow-up study, 80% of patients undergoing staged subcutaneous excision underneath flaps had a significant and long-lasting reduction in extremity size associated with improved function and extremity contour. Wound complications were encountered in 10% of the patients.[35]

A minimally invasive version of the Kontoleon procedure is gaining increasing support among lymphedema experts.[37,38] A number of reports have demonstrated that use of liposuction through small incisions is safe and is able to achieve control, at least on a short-term basis, of clinically disabling conditions associated with advanced stages of lymphedema. Surgeons with experience in this technique recommend initial conservative treatment of pitting lymphedema to remove excess fluid, followed by liposuction to remove remaining excess volume bothersome to the patient.[38]

When the lymphedema is extremely pronounced and the skin is unhealthy and infected, the simple reducing operation of Kontoleon is not adequate. In this case, the classic excisional operation originally described by Charles in 1912 is performed (Fig. 109.6). The procedure involves complete and circumferential excision of the skin, subcutaneous tissue, and deep fascia of the involved leg and dorsum of the foot.[39] The excision is usually performed in one stage, and coverage is provided preferably by full-thickness grafting from the excised skin. In a follow-up report, patients subjected to the Charles operation had immediate volume and circumference reduction. Skin graft take was 88%, and complications of the operation consisted primarily of wound infections,

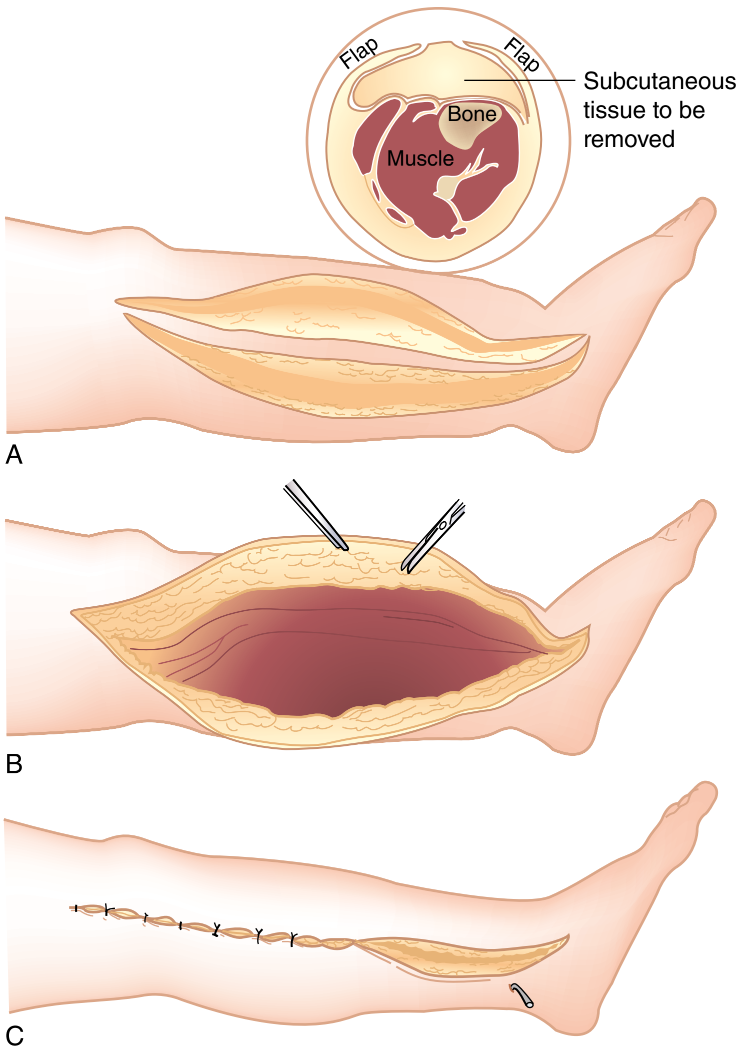

FIGURE 109.5 (A–C) Schematic representation of the Kontoleon or Homan procedure. Relatively thick skin flaps are raised anteriorly and posteriorly, and all subcutaneous tissue beneath the flaps and the underlying medial calf deep fascia are removed along with the necessary redundant skin.

hematomas, and necrosis of skin flaps. The hospital stay was 21 to 36 days.[40] Although this is a successful and radically reducing operation, the behavior in the healing skin graft is unpredictable. Between 10% and 15% of the grafted segments do not take and can be difficult to manage because of frequent localized sloughing, excessive scarring, focal recurrent infections, and hyperkeratosis or dermatitis. These complications seem to be worse in patients in whom leg resurfacing is performed with split-thickness grafts from the opposite extremity. In advanced cases, the exophytic changes within the grafted skin, chronic cellulitis, and skin breakdown may eventually lead to leg amputation.[41]

CHYLOTHORAX

Chylous pleural effusion is usually secondary to thoracic duct trauma (usually iatrogenic after chest surgery) and rarely a manifestation of advanced malignant disease with lymphatic metastasis.[42] Presence of chylomicrons on lipoprotein analysis and a triglyceride level of more than 110 mg/dL in the pleural fluid are diagnostic. Initially, patients can be treated nonoperatively with tube thoracostomy, medium-chain triglyceride (MCT) diet or total parenteral nutrition (TPN), and octreotide/somatostatin therapy.[43] For patients with thoracic duct injury and an effusion that persists after 1 week of treatment with appropriate diet, octreotide, and thoracostomy drainage, an intervention should be considered to identify and occlude the thoracic duct above and below the leak. The operative approach of choice has been video-assisted thoracoscopy or thoracotomy to identify and ligate the thoracic duct above and below the leak (the site of the leak can be identified if heavy cream is given to the patient a few hours before operation). However, a new endoluminal technique has been introduced and is becoming the optimal first approach for the management of persistent postoperative chylothorax. The approach starts with lymphangiography, usually through a groin lymph node access, to identify the location and anatomy of the cisterna chyli and the location of the divided thoracic duct. Once the cisterna chyli is opacified, it is percutaneously accessed with a spinal needle, using radiographic guidance, and is catheterized. The location of the divided thoracic duct is then identified with repeated lymphangiography, and the duct is embolized. In expert hands, this technique has a success rate of more than 50%.[44] For patients with cancer-related chylothorax and persistent drainage despite optimal chemotherapy and radiation therapy, pleurodesis is highly successful in preventing recurrences.

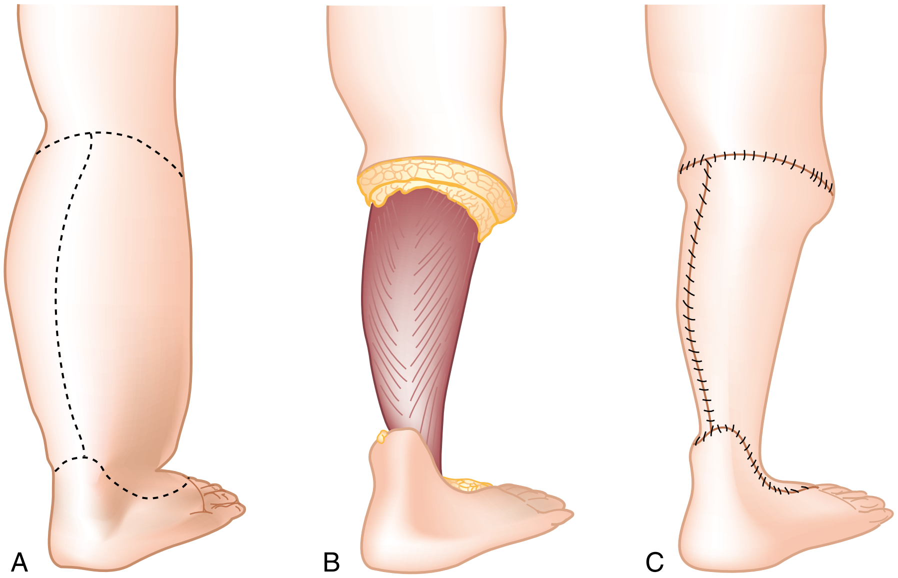

FIGURE 109.6 (A–C) Schematic representation of the Charles procedure. It involves complete and circumferential excision of the skin, subcutaneous tissue, and deep fascia of the involved leg and dorsum of the foot. Coverage is preferably provided by full-thickness grafting from the excised skin.

CHYLOPERITONEUM

In contrast to chylothorax, the most common cause of chylous ascites is congenital lymphatic abnormalities in children and malignant disease involving the abdominal lymph nodes in adults. Postoperative injury to abdominal lymphatics resulting in chylous ascites is rare.[45] Presence of chylomicrons on lipoprotein analysis and a triglyceride level of more than 110 mg/dL are diagnostic. Initial treatment includes paracentesis followed by MCT diet or TPN. In patients with postoperative chyloperitoneum, if ascites does not respond after several weeks of nonoperative management, percutaneous embolization[44] or surgical exploration should be employed to identify and occlude or ligate the leaking lymphatic duct. Conservative management can be successful 77% to 100% of the time using TPN, 75% of the time with MCT diet, and 100% of the time with MCT diet and octreotide. Some authors have recommended TPN initiation with chyle leakage is >200 mL/day and an MCT diet when chyle leakage is <200 mL/day.[46]

Congenital and malignant causes should be given longer periods (up to 4–6 weeks) of nonoperative management. If ascites persists in patients with congenital ascites, lymphoscintigraphy or lymphangiography is performed before an attempt is made to control the leak with laparotomy or laparoscopy. At the time of exploration, control of the leak can be achieved by ligation of leaking lymphatic vessels or resection of the bowel associated with the leak. Patients with malignant neoplasms should receive aggressive management for their underlying disease, which generally is effective at controlling the chyloperitoneum.

TUMORS OF THE LYMPHATICS

Lymphangiomas are the lymphatic analogue of the hemangiomas of blood vessels. They are generally divided into two types: (1) simple or capillary lymphangioma and (2) cavernous lymphangioma or cystic hygroma.[47] They are thought to represent isolated and sequestered segments of the lymphatic system that retain the ability to produce lymph. As the volume of lymph inside the cystic tumor increases, it grows larger within the surrounding tissues. The majority of these benign tumors are present at birth, and 90% of them can be identified by the end of the first year of life. The cavernous lymphangiomas almost invariably occur in the neck or the axilla and very rarely in the retroperitoneum. The simple capillary lymphangiomas also tend to occur subcutaneously in the head and neck region as well as in the axilla. Rarely, however, they can be found in the trunk within the internal organs or the connective tissue in and around the abdominal or thoracic cavities. The treatment of lymphangiomas should be surgical excision, with care taken to preserve all normal surrounding infiltrated structures.

Lymphangiosarcoma, or Stewart-Treves syndrome, is a rare tumor that develops as a complication of long-standing (usually more than 10 years) lymphedema.[48] Clinically, the patients present with acute worsening of the edema and appearance of subcutaneous nodules that have a propensity toward hemorrhage and ulceration. The tumor can be treated, like other sarcomas, with preoperative chemotherapy and radiation followed by surgical excision, which usually may take the form of radical amputation. Overall, the tumor has a very poor prognosis.[49]

Upper Extremity Lymphedema

Primary upper extremity lymphedema is extremely rare. The most common cause of upper extremity lymphedema is breast cancer–related lymphedema (BCRL). This secondary lymphedema is one of the chronic complications after breast cancer treatment. Patients present with symptoms similar to lower extremity lymphedema and describe pain, heaviness, tightness, and decreased range of motion that adversely affects fine motor skills. This can have a significant impact on activities of daily living and work-related tasks. Additionally, this can become a constant reminder of the diagnosis of breast cancer, which can have psychological consequences, including anxiety, depression, and distress. A large systematic review found that 21% of patients undergoing treatment for breast cancer will develop BCRL.[50] This may be an underestimate, given that BCRL can present without arm swelling. Unfortunately, there are no universally accepted diagnostic criteria for BCRL.

Risk factors most associated with this condition include an axillary node dissection with a large number of lymph nodes resected, treatment with a mastectomy, and a higher BMI. Other factors associated with a higher chance of lymphedema included prevalence of more metastatic nodes, receipt of radiation, and an inactive lifestyle with no regular physical activity.[50] Nonoperative and operative approaches have been used for BCRL.[31,32] Lymphatic grafting using thigh lymphatics transferred to the upper extremity is one such approach. Another approach connects lymphatics in the affected upper extremity to neck or chest lymphatics, lymph nodes, or veins. Despite much progress in breast cancer treatment, lymphatic consequences after breast cancer treatment have remained a research gap.[50] Many questions remain, including why 80% of patients do *not* develop lymphedema after breast cancer treatment. This is a field ripe for investigation for the motivated clinician-scientist.

The term *thorax* refers to the area between the neck and abdomen enclosed superiorly by the thoracic inlet; inferiorly by the diaphragm; and radially by the ribs, sternum, and vertebrae. The chest or thorax creates a frame for the neck, arms, thoracic structures, and abdomen; supports and protects the internal thoracic organs; and provides for the negative inspiratory force that initiates ventilation and the positive expiratory force needed for vocalization. The major thoracic structures include the heart and lungs, chest wall—including the overlying musculature, ribs, sternum, and vertebrae—diaphragm, trachea, esophagus, and great vessels.

ANATOMY

The thoracic organs are protected by the bony thorax and overlying chest wall musculature (Fig. 110.1), including the latissimus dorsi, serratus anterior, and pectoralis major and minor. These extrinsic muscles of the chest attach to the bony thorax, protect the chest wall itself, and may assist with ventilatory efforts in patients with chronic obstructive pulmonary disease (COPD).

The thorax has three major interior groups of muscles:

1. **Primary muscles of respiration,** including the diaphragm and intercostal muscles, which occupy the 11 intercostal spaces and consist of the external, internal, and transverse or **innermost muscles**
2. **Secondary muscles of respiration,** including the extrinsic chest wall muscles as previously outlined, as well as the serratus posterior, levatores costarum, and the cervical muscles (sternocleidomastoid and scalenes)
3. **Muscles attaching the upper extremity to the body,** including the pectoralis major and minor anteriorly and the trapezius and latissimus dorsi posteriorly. Deeper muscles include the serratus anterior and posterior, the levatores, and the major and minor rhomboids. In respiratory distress, the deltoid, pectoralis, and latissimus dorsi muscles form a tertiary system for ventilatory assistance through fixation of the upper extremities.

The bony thorax consists of 12 ribs peripherally extending from the vertebrae posteromedially to the sternum (ribs 1–5) or costal arch (ribs 6–10) anteriorly. The 11th and 12th ribs are “floating ribs” and are not attached directly to the sternum. The first rib is relatively flat and dense and travels from the first thoracic vertebra to the manubrium to create the thoracic inlet (Fig. 110.2). This relatively small area contains the great vessels, trachea, esophagus, thoracic duct, and lung apices, along with the phrenic, vagus, and recurrent laryngeal nerves. The remaining ribs

gradually slope downward. Intercostal nerves branch from the spinal roots and innervate the skin and intercostal musculature. The intercostal bundles (vein, artery, and nerve) travel along the lower edge of each rib anteriorly but become centrally located within the intercostal space posteriorly.

The sternum is flat, 15 to 20 cm long, and approximately 1.0 to 1.5 cm thick and comprises the manubrium, sternal body, and xiphoid. The manubrium articulates with each clavicle and the first rib and joins the body of the sternum at the angle of Louis, which corresponds to the anterior aspect of the junction of the second rib. The angle of Louis is a superficial anatomic landmark for the level of the carina and the aortic arch. The anterior cartilaginous attachments of the true ribs to the sternum, along with intercostal muscles and the hemidiaphragms, allow for movement of the ribs with respiration.

The trachea is a semiflexible tube of 1.5 to 2 cm in width and 10 to 13 cm in length, reaching from the lower portion of the larynx at the level of the sixth to seventh cervical vertebra to the fourth to fifth thoracic vertebra, where it bifurcates to form the two bronchi for the lungs. The location of the carina is at the level of the angle of Louis anteriorly and the T4 vertebra posteriorly. The tracheal wall consists of up to 20 incomplete rings of hyaline cartilage, forming the anterior and lateral circumference, and smooth muscle posteriorly known as the *membranous trachea,* which are both embedded into a fibrous membrane of elastic connective tissue. The cricoid is the only complete cartilaginous ring, and the inferior edge marks the end of the larynx. The trachea begins approximately 1.5 cm below the vocal cords and is not rigidly fixed to surrounding tissues. The most rigid point of fixation is where the aortic arch forms a sling over the left mainstem bronchus. The brachiocephalic trunk (innominate artery) crosses over the anterior trachea from left inferolaterally to right superolaterally. The azygos vein arches over the proximal right mainstem bronchus as it travels from posterior to anterior to empty into the superior vena cava. The esophagus runs closely alongside the posterior membranous trachea to the left of the midline, with the recurrent laryngeal nerves located in the tracheoesophageal groove bilaterally. The blood supply to the trachea is posterolateral and segmental from the inferior thyroid, the internal thoracic, the supreme intercostal, and the bronchial arteries. During tracheal resection and reconstruction, great care must be taken to circumferentially dissect only the trachea being removed to avoid vascular insufficiency with necrosis or anastomotic dehiscence. There are approximately 23 divisions of bronchi between the trachea and the terminal alveoli, which make up ~50% of the entire lung volume.

The lungs are broadly divided into five lobes and multiple segments within each lobe (Fig. 110.3). The right lung is composed of three lobes: upper, middle, and lower. The major (oblique) fissure separates the lower lobe from the upper and middle lobes, and the minor (horizontal) fissure separates the upper lobe from the middle lobe. The left lung has two lobes—the upper lobe and the lower lobe—with the lingula corresponding embryologically to the right middle lobe. A single oblique fissure separates the lobes.

The blood supply of the lung is twofold: unoxygenated blood circulates from the right ventricle through the pulmonary artery to each lung, and after oxygenation in the lung parenchyma, the blood is returned to the left atrium through the pulmonary veins. Blood supply to the bronchi is from the systemic circulation by bronchial arteries arising from the superior thoracic aorta or the aortic arch, either as discrete branches or in combination with the intercostal arteries. Although there is variation, there are usually two left bronchial arteries and one right bronchial artery. The bronchopulmonary segments are divisions of each lobe that contain anatomically separate arterial, venous, and bronchial supply. There are ten bronchopulmonary segments on the right and eight bronchopulmonary segments on the left.

Lymphatic vessels are present throughout the lung parenchyma and pleura and gradually coalesce toward the hilar areas of the

lungs. Generally, lymphatic drainage from the lung affects the ipsilateral lymph nodes; however, flow of lymph from the left lower lobe may drain to the right mediastinal (paratracheal) lymph nodes. Lymphatic drainage within the mediastinum drains into the thoracic duct, which originates from the cisterna chyli in the abdomen, and enters the thorax through the aortic hiatus, then travels superiorly to the right of midline along the anterolateral surface of the vertebral column. At approximately the level of T5, it crosses over to the left and continues superiorly to empty into the junction of the left jugular and subclavian veins posteriorly.

The parietal pleura is the internal lining of the chest wall and covers the mediastinum, diaphragm, and pericardium. Its blood supply comes from the systemic arteries and veins, including the posterior intercostal, internal mammary, anterior mediastinal, and superior phrenic arteries and corresponding systemic veins. The lymphatic drainage of the parietal pleura is into regional lymph nodes, including intercostal, mediastinal, and phrenic nodes. It is richly innervated by sensory branches of the intercostal nerves; therefore, generous local anesthesia should be used for chest tube insertion.

The visceral pleura covers the outer surface of the lung and separates the lobes, with blood supply from both systemic and pulmonary sources. Visceral pleural lymphatics follow the superficial lung lymphatics and drain into the mediastinal lymph nodes. The visceral pleura is innervated by vagal branches and the sympathetic system. There is a potential space between the parietal and visceral pleurae that is normally filled with just a scant amount of pleural fluid, which allows nearly frictionless movement during respiration. This pleural space may compress the lungs or heart when filled with fluid, tumor, or infection. The right and left pleural spaces are separated by the mediastinum.

The anatomic boundaries of the mediastinum include the thoracic inlet superiorly, the diaphragm inferiorly, the sternum anteriorly, the vertebral column posteriorly, and the parietal pleural medially. Fat and lymph nodes are found throughout the mediastinum. Traditionally, the mediastinum can be divided into anterosuperior, middle, and posterior compartments. No specific anatomic planes define these areas. The anterosuperior compartment includes the thymus gland. The right and left lobes of the thymus extend into the cervical areas, and these portions of the thymus must be resected to provide for complete extirpation of the gland. The middle mediastinum contains the heart; pericardium; great vessels (including the ascending, transverse, and descending aorta; superior and inferior vena cava. [IVC]; pulmonary artery and veins); trachea and bronchi; and phrenic, vagus, and recurrent laryngeal nerves. The phrenic nerve enters the thorax through the thoracic inlet on the anterior aspect of the anterior scalene muscle.

On the right side, the vagus nerve enters the thoracic inlet through the carotid sheath, lies anterior to the subclavian and posterior to the innominate artery, and continues posteriorly in the tracheoesophageal groove to innervate the trachea and esophagus. The right recurrent laryngeal nerve loops or "recurs" around the innominate artery to innervate the right-sided vocal cord. On the left side, the vagus nerve enters the thorax through the thoracic inlet, and as it exits the carotid sheath, it moves along the anterior aspect of the aortic arch and continues within the mediastinum along the esophagus posteriorly to innervate both the trachea and the esophagus. The left recurrent laryngeal nerve arises from the vagus nerve, loops around under the ligamentum arteriosum, continues superiorly under the aorta, and lies in the tracheoesophageal groove as it courses to innervate the left-sided vocal cord.

The posterior mediastinum lies between the heart/pericardium and trachea anteriorly and the vertebral column and paravertebral spaces posteriorly. It contains the esophagus, descending aorta, azygos and hemiazygos veins, thoracic duct, sympathetic chain, and lymph nodes.

The inferior border of the mediastinum is the diaphragm, which separates the abdominal contents from the thorax. Hernias through the esophageal hiatus (paraesophageal hernias), through the foramen of Bochdalek (posteriorly), or through the foramen of Morgagni (anteriorly) may be initially identified as a mediastinal mass.

The spinal root divides as it exits the neural foramina. One branch goes to the intercostal nerve, and one lies in the posterior vertebral gutter to form the sympathetic ganglion. The thoracic sympathetic trunk comprises several ganglia that lie along the ribs. The most superior ganglion is the stellate ganglion.

SELECTION OF PATIENTS FOR THORACIC OPERATIONS

The physiologic evaluation of the thoracic surgical patient must be individualized and generally emphasizes the pulmonary and cardiac function. The assessment of a patient's ability to tolerate lung resection from a cardiopulmonary standpoint is fundamental to patient selection for surgery. Patients with advanced pulmonary disease and severe pulmonary dysfunction may have prohibitive risk, which may exist in greater than one-third of patients with otherwise resectable lung disease.[1] However, many patients with poor nutrition or pulmonary function can optimize functional status and postoperative outcomes through targeted prehabilitation programs.

Cigarette smoking is associated with increased postoperative pulmonary complications. If the patient is a smoker, they must stop smoking immediately. Although there are few studies specific to pulmonary resection, there is evidence that smoking abstinence 4 to 8 weeks before surgery is necessary to reduce complication rates. However, smoking cessation at any time is valuable and should be encouraged. Smoking cessation programs may be helpful for these patients because many patients require pharmacologic assistance and ongoing counseling to achieve durable abstinence.[2]

In the pre- and perioperative periods, deep venous thrombosis prophylaxis should be provided with subcutaneous heparin or low-molecular-weight heparin and sequential compression stockings. Standard perioperative antibiotics should be administered before incision to reduce surgical site infections.

Aggressive multimodal analgesia can reduce perioperative morbidity by facilitating early ambulation. Standard regimens commonly include Tylenol, NSAIDs, regional pain management with thoracic epidural catheter or intercostal rib blocks with long-acting local anesthetics, and/or patient-controlled analgesia.[3]

Regular incentive spirometry assists in expanding the lung and reducing the incidence of pulmonary morbidity. Nasal bilevel positive airway pressure for patients with obstructive sleep apnea may delay or eliminate the need for intubation or reintubation after pulmonary resection, although caution should be exercised for patients with foregut anastomoses.

Physiologic Evaluation

Patients may be evaluated preoperatively with a combination of radiographic and physiologic studies. A plain chest x-ray (CXR) is commonly obtained and serves as a baseline study that may be

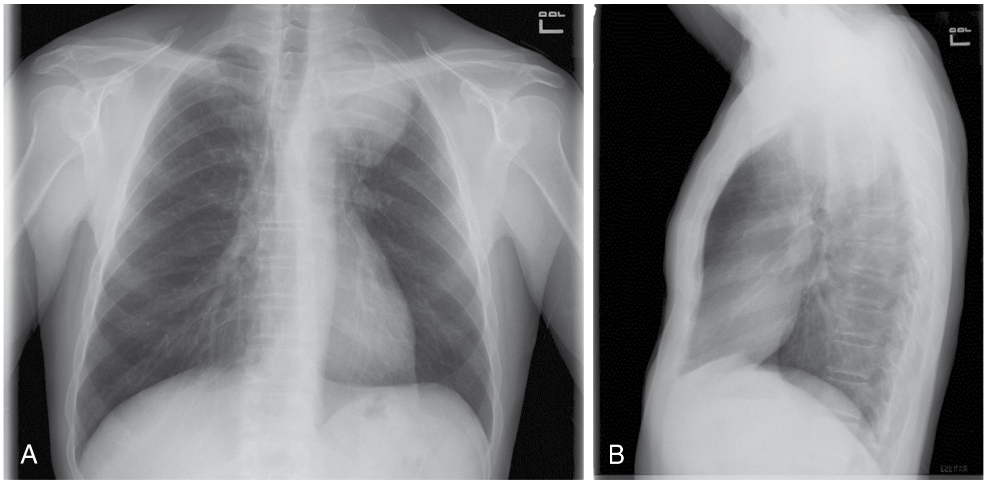

FIGURE 110.4 Initial chest x-rays. This patient is a 67-year-old male with a weight loss of 10 pounds in 4 weeks and a 35-pack-year history of cigarette smoking. He quit smoking 10 years ago. He had left shoulder pain for 4 months with no dyspnea, cough, hemoptysis, or other symptoms. Massage and other musculoskeletal manipulation did not improve his symptoms. A chest x-ray with posteroanterior (A) and lateral (B) views demonstrates an 8.4-cm left upper lung mass. Some deviation of the distal trachea is noted.

referenced postoperatively (Fig. 110.4). Preoperative anemia is associated with adverse operative outcomes, so care must be taken to identify and correct reversible causes of anemia, such as iron deficiency. Spirometry measures the lung volumes (Fig. 110.5) and the mechanical properties of lung elasticity, recoil, and compliance.

Pulmonary function testing (Fig. 110.6) also evaluates gas exchange functions, such as carbon monoxide diffusing capacity (DLCO) and the predicted postoperative forced expiratory volume in 1 second (FEV$_1$). FEV$_1$ is the most common indicator of postoperative pulmonary reserve; most patients with FEV$_1$ greater than 60% predicted can tolerate an anatomic lobectomy and do not require further pulmonary function testing. If FEV$_1$ is less than 60% of predicted, quantitative radionucleotide lung perfusion testing (Fig. 110.7) can provide a measurement of the relative function of each lobe and lung and allows an estimation of pulmonary function after lung resection (ppoFEV$_1$):

ppoFEV$_1$ = preopFEV$_1$ × (1 – fraction of perfusion to region of planned resection)

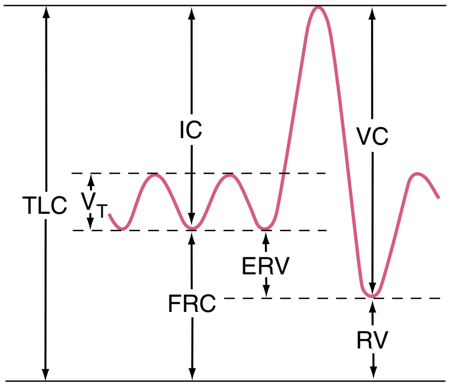

FIGURE 110.5 Spirometry with subdivisions of lung volumes. *ERV,* Expiratory reserve volume; *FRC,* functional residual capacity (i.e., lung volume at end expiration); *IC,* inspiratory capacity; *RV,* residual volume (i.e., lung volume after forced expiration from FRC); *TLC,* total lung capacity; *VC,* vital capacity (i.e., maximal volume of gas inspired from RV); *V_T,* tidal volume.

A ppoFEV$_1$ of 40% or less carries a greater risk for postoperative dependence on supplemental oxygen and/or mechanical ventilation. It should be noted that the ppoFEV$_1$ is not likely to be realized in the immediate postoperative period, secondary to pain and limited ambulation.

DLCO is most commonly assessed using the single-breath test, which measures the rate at which test molecules, such as carbon monoxide, move from the alveolar space to combine with hemoglobin in the red blood cells. The difference between inspired and expired samples of gas is used to calculate DLCO. Levels less than 50% are associated with increased perioperative risk.

Flow-volume loops derived from spirometry describe the relationship between lung volume and airflow as the lung volume changes during a forced expiration and inspiration. The typical test consists of tidal breathing at rest, followed by maximal inspiratory effort to total lung capacity, then maximal expiratory effort to residual volume, concluding with maximal inspiratory effort to total lung capacity. In obstructive lung disease, the ratio of FEV$_1$ to forced vital capacity (FVC; FEV$_1$/FVC) is low (FEV$_1$ is low, and FVC is high); in restrictive disease, the ratio is about normal because both FEV$_1$ and FVC are reduced.

Cardiopulmonary exercise testing (CPET) can be extremely useful in the evaluation of frail or functionally marginal surgical candidates. CPET includes exercise electrocardiography, heart rate response to exercise, and measurements of minute ventilation and oxygen uptake. Calculation of maximal oxygen consumption (VO$_2$ max) provides insight into overall cardiopulmonary function (the "cardiopulmonary axis") and may identify clinically occult cardiac disease. Overall, CPET provides a more accurate assessment of pulmonary function than spirometry and DLCO, which tend to overestimate functional loss after resection.

A patient's risk of perioperative morbidity and mortality may be stratified by measurement of VO$_2$ max. A level less than 11 to 15 mL/kg/min is associated with an increased risk, and VO$_2$ max less than 10 mL/kg/min indicates high risk.[4] An inexpensive and readily available test that can be performed in the clinic is a stair-climbing test. Patients who can walk 18 m have reduced perioperative complication rates and improved survival after lung cancer resection.[5]

Interpretation

Spirometry reveals an isolated reduction in mid-expiratory flows consistent with an obstructive small airways defect. Increased residual volume (RV) is consistent with air trapping. Following the inhalation of a bronchodilator, there is no improvement of the obstructive airway defect. The diffusing capacity is normal.

FIGURE 110.6 The pulmonary function report provides complete spirometry data based on predicted values for height and weight. In this patient, the forced expiratory volume in 1 second *(FEV$_1$)* is 2.26 L after bronchodilators, which is 80% of predicted. The carbon monoxide diffusing capacity *(DLCO)* is measured as 23.81 mL/min/mm Hg, which is 105% of predicted. *FEF,* Forced expiratory flow; *FIV$_1$,* forced inspiratory volume in one second; *FIVC,* forced inspiratory vital capacity; *FRC,* functional reserve capacity; *FVC,* forced vital capacity; *Hb,* hemoglobin; *PEF,* peak expiratory flow; *SB,* single breath; *SVC,* slow vital capacity; *TLC,* total lung capacity; *VA,* alveolar volume; *VC,* vital capacity.

Measurement of diaphragm function by fluoroscopy, the “sniff test,” or ultrasonography is needed to determine symmetry of effort and to exclude paradoxical movement of the diaphragm. Paradoxical movement (elevation of one hemidiaphragm with active contraction/retraction of the other diaphragm) suggests paresis or paralysis, and diaphragm plication may be therapeutic.

No single test result should be viewed as an absolute contraindication to surgical resection. Patients with marginal preoperative pulmonary and general functional assessments must be considered thoughtfully on an individual basis.

Thoracic Incisions

The choice of incision depends on the operation, the patient’s underlying physiologic condition, and the anticipated benefits and limitations of the planned approach. Video-assisted thoracoscopic surgery (VATS), robotic-assisted thoracoscopic surgery (RATS), and other minimally invasive surgical techniques have been developed to treat most thoracic problems, including lung and esophageal cancer, mediastinal tumors, pleural diseases, and parenchymal diseases, and to diagnose and stage thoracic malignancies. Various small incisions are made for the camera and other instruments depending on the location of the lesion. To accommodate the instruments, careful attention must be paid to incision placement relative to the patient’s ribs, arm, diaphragm, and scapula. The ribs are not spread. Improved lighting and optics create excellent exposure and visualization, often superior to that achieved with an open approach. Patient advantages of minimally invasive surgical techniques include reduced postoperative pain and length of hospitalization.

FIGURE 110.7 The quantitative perfusion lung scan report provides the lung volume and the perfusion to each lung. In a patient with a large left hilar tumor, perfusion may be reduced in the involved left lung compared with the uninvolved right lung. The predicted post–left pneumonectomy right lung function can be obtained by multiplying the right lung percent perfusion (58.2%) by the observed best forced expiratory volume in 1 second (FEV_1; 2.26 L). The resulting value, 1.31 L, 46.5% predicted, is the predicted postoperative FEV_1 (after left pneumonectomy). This value suggests that a left pneumonectomy would be functionally tolerated. *Ll,* Left lower zone; *Lm,* left middle zone; *Lu,* left upper zone; *Rl,* right lower zone; *Rm,* right middle zone; *Ru,* right upper.

Open thoracotomy requires spreading the ribs with a retractor and is used for operations on a single side of the thorax. The patient is placed in a lateral decubitus position, and the incision may be posterior, axillary, or anterior. For posterior access, an oblique incision is used with or without sparing the latissimus dorsi muscle. The chest is typically entered through the fifth interspace. For anterior hilar exposure, a vertical axillary incision can be made anterior to the latissimus dorsi muscle, and the chest is entered through the fourth interspace. For anterior or anterolateral access, a curvilinear incision is created underneath the inferior border of the pectoralis major muscle at the inframammary fold.

Median sternotomy is performed using a vertical incision from the sternal notch to the xiphoid. A sternal saw is then used to divide the sternum in the midline. With gentle retraction, the sternum can be spread approximately 8 to 10 cm to allow access to the mediastinum, heart, great vessels, and right and left thorax. The pleura can be opened on either side to explore the hemithorax. The sternum is usually closed with stainless-steel wire. Sternotomy is commonly used for cardiac surgery, mediastinal tumors, and tracheal/carinal exposure and occasionally for pulmonary resection.

A transverse sternotomy, or “clamshell” incision, is larger than a median sternotomy and typically more painful postoperatively for the patient. This incision combines two anterior thoracotomy incisions in the inframammary fold with transverse division of the sternum at the fourth intercostal space. Both internal mammary arteries are ligated. This approach is ideal for accessing both the right and the left hilum and providing additional exposure for large mediastinal tumors, bilateral hilar dissections, or bilateral lung transplantation.

LUNG DEVELOPMENT

Lung development begins at approximately 21 to 28 days’ gestation, and disturbed embryogenesis can result in various congenital lung abnormalities. They comprise a spectrum of anomalies, with one end representing abnormal lung parenchyma supplied by normal vessels, such as unilateral pulmonary agenesis and pulmonary hypoplasia. The other end of the spectrum represents normal lung parenchyma supplied by abnormal vessels. Hybrid lesions are common. Clinically, these lesions are most often asymptomatic but can cause respiratory failure.

Congenital Cystic Lesions

Congenital cystic lesions consist of congenital pulmonary airway malformations (CPAMs) or congenital cystic adenomatoid malformations, pulmonary sequestrations, congenital lobar emphysema, and bronchogenic cysts. Approximately one-third are asymptomatic, one-third have cough, and one-third have infection. Treatment may be with antibiotics or, for more severe localized cases, with resection. Any cystic lesion that enlarges on serial radiographs needs to be considered for resection.

Cystic fibrosis (CF) is an autosomal recessive disorder that is found more commonly in White patients. Excessively thick mucus leads to recurrent infections, bronchitis, and bronchiectasis. The treatment of CF is rapidly evolving, and the recent introduction of cystic fibrosis transmembrane conductance regulator (CFTR) modulators that target the underlying mutant protein has effectively slowed the rate of disease progression in eligible patients. Nevertheless, lung failure remains the most common cause of death. Bilateral lung transplantation should be considered when the disease rapidly progresses and the remaining pulmonary reserve is low. Early referral to a transplant program is important to maximize potential benefit.

CONGENITAL ABNORMALITIES OF THE TRACHEA AND BRONCHI

Tracheoesophageal fistula, commonly with esophageal atresia, is the most frequent abnormality of the trachea in infants (see Chapter 117), followed by bronchial atresia.[6] Complete tracheal agenesis is a rare phenomenon and is fatal. It results from abnormal development of the laryngotracheal groove, and the trachea is absent from the larynx to the carina, with communication between the bronchi and the esophagus.

Tracheal stenosis is also rare and results from complete or near-complete rings of tracheal cartilage with an absent membranous component. Infants typically present with respiratory distress, cyanosis, and feeding difficulties. Surgical repair of the trachea is by vertical incision and widening of the tracheal lumen.

Tracheomalacia represents dynamic collapse of the trachea during respiration, resulting in airway obstruction. It is classified as congenital (primary) or acquired (secondary) and can be identified by diagnostic imaging (dynamic expiratory computed tomography [CT]) or bronchoscopy, which reveals marked variation of the tracheal lumen with inspiration and expiration. Collapse of greater than 70% of the lumen during expiration is diagnostic. Clinical presentation depends on the location and severity of tracheal collapse. Relief of the extrinsic compression is needed for symptomatic improvement. Procedural intervention is indicated for life-threatening airway obstruction, recurrent infection, respiratory failure, or failure to thrive. Treatment may include stent placement, posterior splinting, or primary tracheobronchoplasty. Individually customized 3D-printed airways are a developing technology for airway management.

CONGENITAL VASCULAR DISORDERS

Several congenital disorders of the pulmonary vasculature may occur.[7] In Swyer-James-Macleod syndrome, idiopathic hyperlucent lung tissue results from diminished pulmonary arterial blood supply. It develops uncommonly after chronic pulmonary infections with associated bronchiolitis obliterans. Treatment is typically nonoperative but may include pneumonectomy for patients with severe bronchiectasis.

Scimitar syndrome is characterized by an anomalous direct venous connection (called the *scimitar vein*) between the right pulmonary vein and the IVC. The affected lung and its airways, which are also drained by the scimitar vein, are hypoplastic, with atypical bronchial and vascular distributions. It is commonly associated with bronchopulmonary sequestration and hypoplastic left heart syndrome. Surgical repair involves a patch from the pulmonary vein to the left atrium and is usually completed with the use of intraoperative extracorporeal membrane oxygenation (ECMO).

Pulmonary arteriovenous malformations (PAVMs) may exist as one or multiple connections from the pulmonary artery to the pulmonary vein, bypassing the pulmonary capillary bed and producing a right-to-left shunt. Most commonly, they are seen in hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome). This diagnosis should be considered for any patient with hemoptysis without other etiology identified by bronchoscopy or other imaging modalities. Small asymptomatic lesions may be managed with observation and serial imaging. For large and/or symptomatic lesions, catheter embolization is the primary treatment. Local resection may be considered in patients with poorly accessible lesions, in patients with severe untreatable contrast allergy, or after failed embolization.

Pulmonary artery sling consists of an anomalous or aberrant left pulmonary artery that arises from the right (main) pulmonary artery and courses between the trachea and the esophagus to supply the left lung. This causes compression of the trachea and/or esophagus. Surgical correction requires relocation of the left pulmonary artery from its right-sided origin to the main pulmonary artery. It is often seen with other congenital anomalies; if it co-occurs with tracheal stenosis, segmental tracheal resection or tracheoplasty should be performed concurrently with vascular reconstruction.

Vascular rings constitute 7% of all congenital cardiac malformations.[8] Most patients require operation within the first weeks or months of life. Patients with vascular rings require a careful history and barium swallow for diagnosis. Bronchoscopy and esophagoscopy are not routinely ordered, but echocardiography, CT scanning, and MRI may be used to further delineate the anatomy.

The most common vascular ring is a double aortic arch (60% of cases). The right or posterior arch is larger and gives rise to the right carotid and right subclavian arteries, wrapping around both the trachea and the esophagus. A posterior indentation is noted in the esophagus on barium swallow. Simple division of the smaller arch corrects the anomaly.

The next most common vascular ring is a right aortic arch with a left ligamentum arteriosum (25%–30% of all vascular rings). Among these patients, two-thirds have a retroesophageal left subclavian artery, and one-third have mirror-image branching, with the left carotid and subclavian arteries arising from the left innominate artery. Alternately, a retroesophageal right subclavian artery with left ligament may occur. The patient may complain of dysphagia, which is referred to as *dysphagia lusoria.* The differential diagnosis includes neuromotor diseases of the esophagus and stricture. Surgical repair is indicated for symptomatic cases and involves left thoracotomy in the fourth intercostal space and division of the ligamentum, allowing the trachea and the esophagus to be freed from surrounding tissues.[9]

LUNG CANCER

Lung cancer refers to malignancies of the pulmonary parenchyma and airways. Cigarette smoking is unequivocally the most important risk factor in the development of lung cancer. Secondhand smoke is also a significant risk factor. Other environmental factors may predispose to lung cancer. Environmental radon gas exposure is estimated to be the second most important risk factor. Other factors include asbestos, arsenic, chromium, nickel, organic chemicals, iatrogenic radiation exposure, air pollution, secondary smoke from nonsmokers, and prior chest radiation therapy (e.g., for Hodgkin lymphoma or breast cancer).

Despite advances in diagnosis and treatment, lung cancer remains a significant global health problem, with a global incidence of 2.2 million cases and 1.8 million deaths in 2020.[10] In the United States, lung cancer is the leading cause of cancer-related deaths for both males and females, accounting for 26% of cancer-related deaths and exceeding the number of deaths from breast, prostate, and colorectal cancer combined. Lung cancer incidence rates have decreased by ~2.2% per year since 2008, likely as a result of programs aimed at smoking cessation. However, smoking cessation in females has lagged behind smoking cessation in males; thus, the incidence of lung cancer in females has not declined as much as the incidence in males (Fig. 110.8). Mortality has declined in recent years, likely as a result of improved screening and treatment options, especially for non–small cell lung cancer. However, demographic disparities exist, with African American males having both the highest incidence and the highest death rate from cancer of the lung and bronchus.[11]

Optimal treatment of lung cancer depends on stage and cancer type. Staging is based on the extent of tumor, lymph node, and metastatic disease (tumor-node-metastasis [TNM] system). The system is internationally recognized and used for prognostication and to guide treatment decisions.

Pathology

In 2021 the World Health Organization (WHO) issued a revised classification of tumors of the lung, replacing the previous 2015 guidelines. The 2021 edition includes a broader emphasis on genetic testing, expanded commentary on the classification of small diagnostic samples, and modernized recommendations on subtype classification based on immunohistochemical profiling of small tumor biopsies and cytologies. The major types of malignant tumors of the lung are adenocarcinomas, squamous cell carcinomas (SCCs), large cell carcinomas, sarcomatoid carcinoma, and neuroendocrine tumors (NETs) of the lung; each of these groups has multiple subtypes that differ by their morphologic, genetic, and biologic properties. Key characteristics of these tumors are described next.

Adenocarcinomas are malignant epithelial tumors with glandular differentiation or mucin production, showing acinar, papillary,

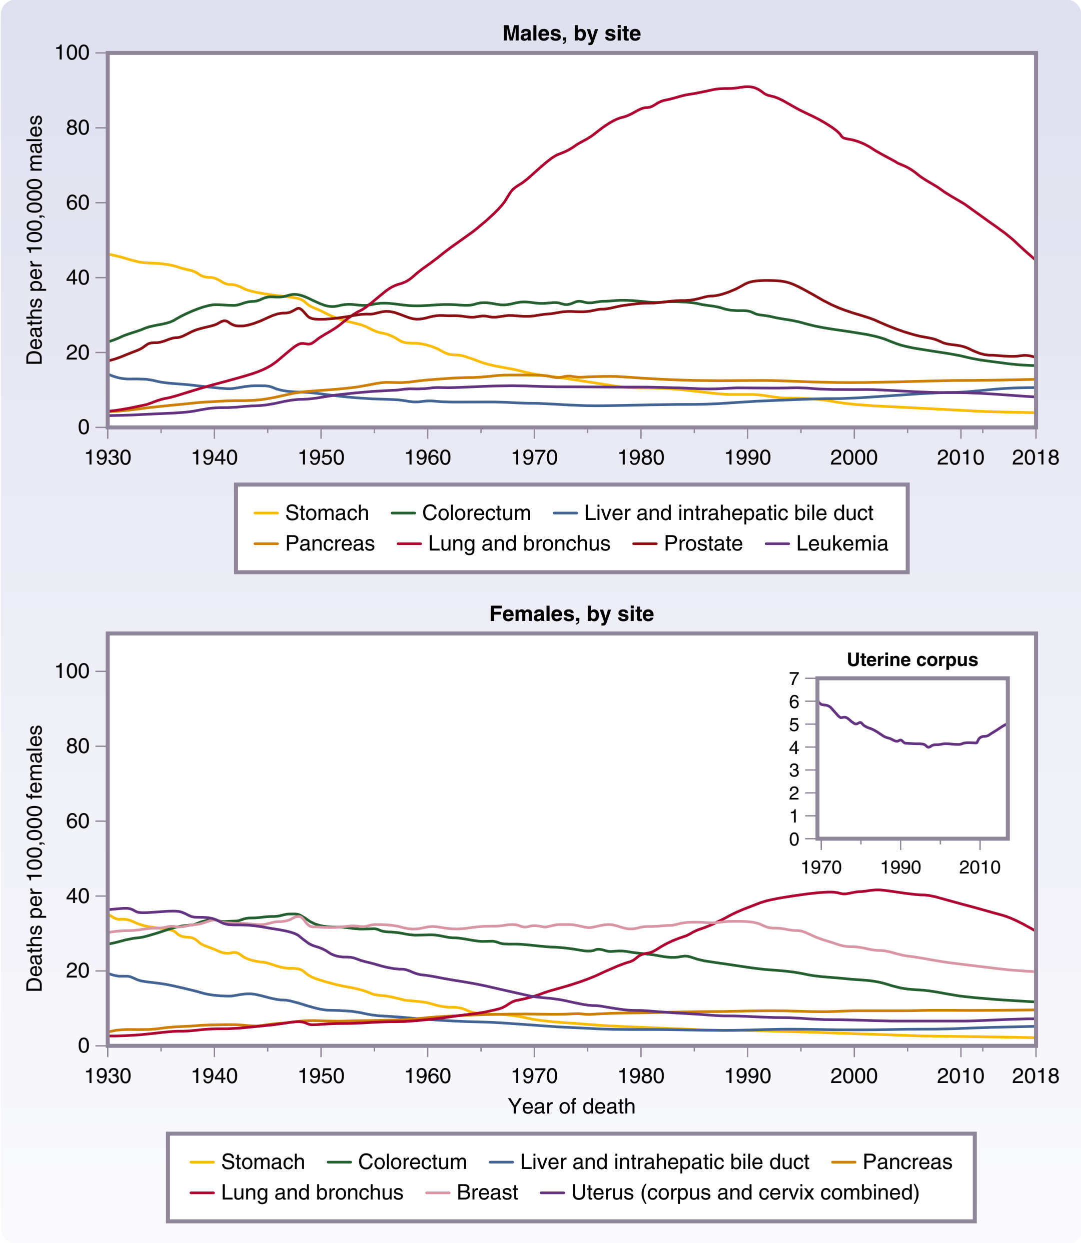

FIGURE 110.8 Trends in cancer death rates by sex for selected cancers, United States 1930 to 2018. Rates are age adjusted to the 2000 US standard population. (From Siegel RL, Miller KD, Jemal A. Cancer statistics, 2018. *CA Cancer J Clin.* 2018;68:7-30.)

micropapillary, lepidic (bronchioloalveolar), or solid with mucin growth patterns or a mixture of these patterns. Adenocarcinoma of the lung is the most frequent histologic type of lung cancer, accounting for approximately half of all lung cancers. Microscopic features consist of cuboidal to columnar cells with adequate to abundant pink or vacuolated cytoplasm and some evidence of gland formation. Most of these tumors (75%) are peripherally located. Adenocarcinoma of the lung tends to metastasize earlier than SCC of the lung and more frequently to the central nervous system. Some adenocarcinomas can present as ground-glass opacities and are not associated with tobacco use. These tumors are increasing in frequency and are more common in females and people from Asia.

SCC is a malignant epithelial tumor showing keratinization and/or intercellular desmosome ("bridges") that arises from bronchial epithelium. Approximately 30% of lung cancers are SCCs, and among these, over 90% occur in cigarette smokers. Approximately two-thirds of these tumors are centrally located and tend to expand against the bronchus, causing extrinsic compression. SCCs are prone to undergo central necrosis and cavitation. SCC tends to metastasize later than adenocarcinoma. Microscopically, keratinization, stratification, and intercellular bridge formation are exhibited. SCC may be more readily detected on sputum cytology than adenocarcinoma.

A diagnosis of large cell undifferentiated carcinoma may be made when specific cytologic features of SCC or adenocarcinoma or neuroendocrine differentiation are lacking. These tumors are typically large and peripherally located and tend to metastasize relatively early. Microscopically, these tumors show sheets of round to polygonal cells with prominent nucleoli and abundant pale-staining cytoplasm without differentiating features.

NETs of the lung share specific morphologic, ultrastructural, immunohistochemical, and molecular features; they arise from cells derived from the embryologic neural crest. This group of tumors includes small cell lung carcinomas (SCLCs), large cell neuroendocrine carcinomas, and typical and atypical carcinoids. Typical carcinoids show a relatively indolent growth pattern, whereas small cell carcinomas and large cell neuroendocrine carcinomas are highly aggressive.

Small cell lung cancers represent approximately 20% of all lung malignancies; 80% of these tumors are centrally located and tend to spread early to mediastinal lymph nodes and distant sites, especially the bone marrow and brain. Microscopically, the tumors appear as sheets or clusters of cells with dark nuclei and little cytoplasm. Neurosecretory granules are evident on electron microscopy. Small cell lung cancer is staged according to the lung cancer TNM staging system; however, from a clinical perspective, the disease may also be addressed as limited stage (disease restricted to an ipsilateral hemithorax within a single radiation port) and extensive stage (obvious metastatic disease). Staging includes 18F-fluorodeoxyglucose–positron emission tomography (FDG/PET), brain CT or MRI, and mediastinoscopy. Mediastinal metastases on clinical staging suggest advanced disease, which is best treated with chemoradiotherapy.[12,13] These tumors are generally advanced at presentation, with an aggressive tendency to metastasize, so chemoradiotherapy is often the first-line therapy. Prophylactic cranial irradiation aimed at reducing the risk of brain metastases is considered in patients with limited or extensive disease that responds well to first-line therapy. Complete responses may occur in ~30% of patients; however, the 5-year survival rate is only 5%. Patients with very early stage disease (e.g., <3 cm in size, no nodal metastases, and no extrathoracic metastases) may be considered for surgical resection, followed by adjuvant systemic therapy.

Lung cancers commonly metastasize to the pulmonary and mediastinal lymph nodes (lymphatic spread). Hematogenous spread of lung cancer commonly results in metastases to the adrenal glands, liver, brain, lung, and bone. Adenocarcinoma is more likely to metastasize to the central nervous system. Bone metastases are osteolytic. Extrathoracic metastases may occur without hilar nodes or mediastinal metastases.

Screening

Patients with lung cancer often present with advanced stage and symptoms. The pulmonary parenchyma does not contain nerve endings, and therefore, tumors may grow undetected until late-stage symptoms of pain, hemoptysis, or obstructive pneumonia arise. Clinical outcomes are directly related to the stage at the time of diagnosis, as reflected by 5-year survival with clinical stage IA1 (92%) compared with clinical stage IVB (approaching 0%). With the increased use of CT in the United States, smaller asymptomatic lung cancers are being identified.

The US National Lung Screening Trial (NLST) was a prospective randomized multicenter study evaluating annual low-dose helical CT with annual chest radiography for older adults with heavy smoking histories. Patients who received annual low-dose CT screening had reduced lung cancer–specific mortality and all-cause mortality compared with those who underwent annual CXR. In fact, the study was closed early on the basis of clear, statistically significant mortality benefit of CT screening.[14] Similarly, the European NELSON lung cancer screening trial was a randomized controlled trial comparing low-dose CT screening for high-risk older adults at increasing intervals to no screening. Overall, the study demonstrated that the use of CT screening among high-risk asymptomatic patients reduced lung cancer deaths at 10 years, with an improved benefit in females compared with males. Several other international randomized trials (including the Detection and Screening of Early Lung Cancer with Novel Imaging Technology and Molecular Assays [DANTE] trial and the Multicentric Italian Lung Detection Study in Italy, the Danish Randomized Lung Cancer CT Screening Trial in Denmark, the German Lung Cancer Screening Intervention Study in Germany, the UK Lung Cancer Screening pilot trial in the United Kingdom, and a 2020 meta-analysis) all demonstrated benefit of CT in screening for individuals at high risk of developing lung cancer.

Based on these results, screening for early lung cancer detection using low-dose helical CT is recommended for high-risk individuals. The guidelines differ slightly based on the expert consensus of various groups internationally. In the United States, the National Comprehensive Cancer Network (NCCN) recommends low-dose chest CT screening for individuals aged ≥ 50 years with a ≥ 20-pack-year smoking history of smoking tobacco who are either current or former smokers.[15,16] The US Preventive Services Task Force guidelines recommend low-dose CT screening for adults aged 50 to 80 years with a 20-pack-year smoking history and who currently smoke or have quit within the past 15 years. The American Cancer Society recently released new guidelines, now recommending screening for adults aged 50 to 80 years with a ≥ 20-pack-year smoking history, which is broadened from previous guidelines.[17] Despite clear clinical benefit of screening and increasingly broad international guidelines from all major expert consensus groups, uptake of lung cancer screening in clinical practice has been low. Black patients are less likely to receive annual lung cancer screening than White patients,[18] likely contributing to racial disparities in lung cancer mortality.

Physicians should discuss testing for early stage lung cancer with their patients. This discussion should include the risks, benefits, and limitations associated with lung cancer screening with low-dose helical CT and should occur before a decision is made to start any lung cancer screening. Screening of asymptomatic patients may identify nonspecific findings, such as overdiagnosis of benign nodules, which could result in patient anxiety and additional radiation exposure. Nevertheless, the benefit to high-risk patients likely outweighs these risks, and patients should be supported by adhering to consensus screening guidelines and subsequent follow-up care for identified pulmonary nodules.

Diagnosis

The diagnosis of lung cancer can be challenging because many benign conditions mimic lung cancer. Physical examination should focus on the cardiorespiratory system and signs of metastasis (e.g., weight loss, pain, headaches, seizures, anemia). In addition, the presence of lymphadenopathy, identified by a careful examination of the cervical and supraclavicular lymph nodes, may suggest advanced disease (N3 lymph node descriptor). Paraneoplastic syndromes are distant manifestations of lung cancer (not metastases), as revealed in extrathoracic nonmetastatic symptoms that can include muscle, nerve, bone, and the endocrine system.

Non–small cell lung cancer (NSCLC) typically occurs in patients who are 50 to 70 years old with a history of cigarette smoking. Patients develop symptoms based on the physical impact of tumor growth within the lung parenchyma. Symptoms such as cough, dyspnea, chest wall pain, and hemoptysis are related to the physical presence of the tumor and its interactions with the structures of the lung and chest wall.[19] The majority of early stage lung cancers are asymptomatic and detected by screening or identified incidentally on routine chest imaging for other indications.

Once a clinical suspicion for NSCLC arises, the clinician should aim to achieve a timely diagnosis and accurate staging so that appropriate therapy can be administered—ideally within 6 to 12 weeks of first suspicion. The workup of a primary solitary pulmonary nodule (SPN) involves a combination of imaging modalities, including CT and PET/CT (Fig. 110.9), and usually a biopsy. Under certain circumstances, an SPN may be deemed benign with adequate confidence in the absence of biopsy with pathologic diagnosis. SPNs that are entirely calcified, or are radiologically solid and stable on CT for a minimum of 2 years, are very likely to be benign. Review of old CT scans or other prior imaging studies is essential in the management of these patients.[20]

In patients with a clinically suspicious SPN, biopsy with pathologic assessment may be needed to guide further management. The preferred sampling strategy is the least invasive method compatible with obtaining a diagnosis. Diagnostic bronchoscopy, transthoracic needle aspiration, or navigational bronchoscopy can be selected based on the size, location, and condition of the patient. In a physiologically fit patient with a highly suspicious yet undiagnosed SPN, nonanatomic wedge or sublobar resection can provide a diagnosis. When appropriate, frozen section confirmation of NSCLC by the pathologist may be followed by definitive (anatomic) resection in the same operative setting. For an SPN in the absence of a cancer diagnosis (that cannot be removed by wedge resection), a lobectomy can be considered for diagnosis (and treatment). However, a pneumonectomy should not performed without a cancer diagnosis.

One-third of patients with NSCLC may have a pleural effusion at the time of presentation. Pleural fluid sampling with thoracentesis is required for cytologic examination. Malignant pleural effusion (MPE) is a contraindication to resection, but many pleural effusions in this setting may be reactive in origin.[21]

Bronchoscopy is recommended before any planned pulmonary resection. The surgeon independently assesses (via bronchoscopy) the endobronchial anatomy to exclude secondary endobronchial primary tumors and to ensure that all known cancer will be encompassed by the planned pulmonary resection. Secretions can be cleared with suctioning and gentle irrigation. When pneumonectomy or bronchoplastic resection is contemplated for a central tumor, the surgeon's assessment at bronchoscopy is critical to the determination of whether complete (R0) resection can be achieved.

If the patient has hard palpable lymph nodes in the cervical or supraclavicular area, fine-needle aspiration or biopsy may provide an accurate diagnosis of N3 disease (Fig. 110.10).

Staging

Staging describes the extent of the cancer and provides prognostication based on outcome patterns for patients with similar

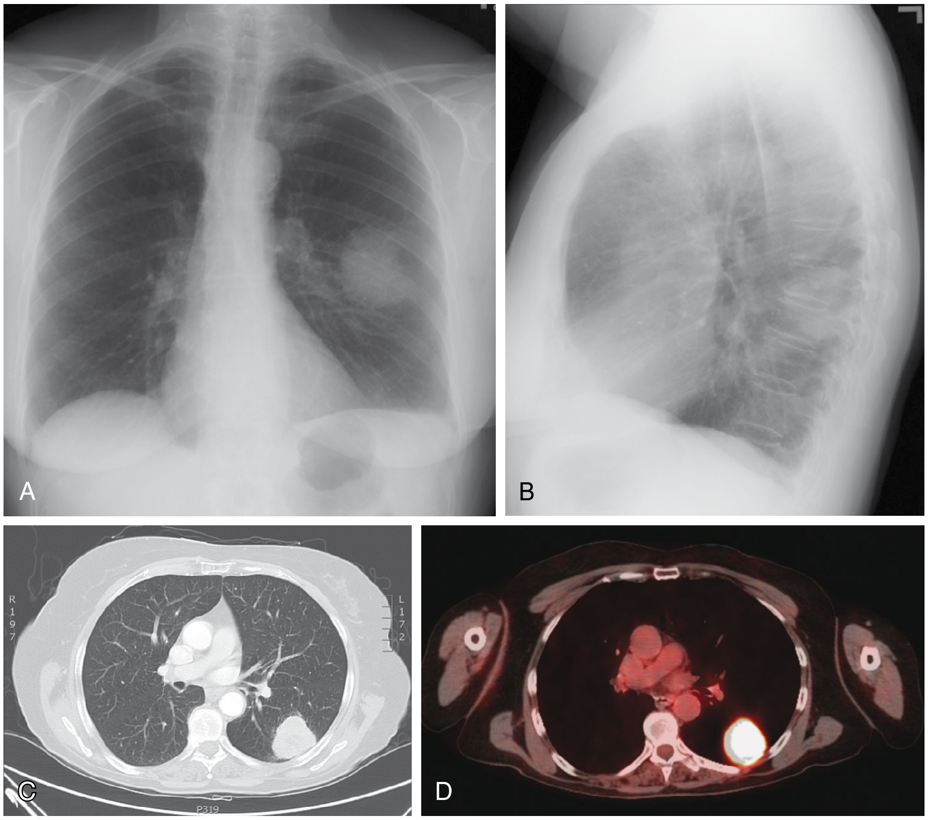

FIGURE 110.9 Radiographic evaluation for any patient with known or suspected lung cancer includes a plain chest x-ray, posteroanterior (A) and lateral (B) views. Evaluation of the plain films and computed tomography (CT) (C) guides subsequent evaluations. F-fluorodeoxyglucose positron emission tomography (FDG-PET) with fused CT (D) provides the ability to correlate metabolic activity with physical findings. Although FDG-PET uses the increased metabolism in most neoplasms to create the FDG-PET image, other process (such as infection, inflammation, or sequelae of trauma or fractures) can be identified as well. Sites of increased metabolism should be carefully evaluated for metastases.

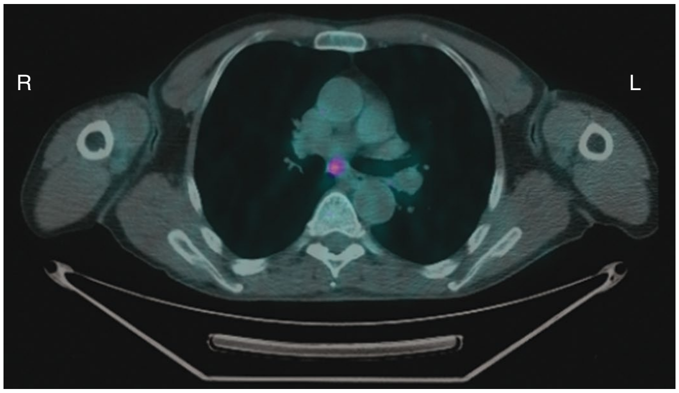

FIGURE 110.10 A subcarinal lymph node has mild ^{18}F-fluorodeoxyglucose (FDG) uptake. Based on these findings, additional invasive staging is warranted, including bronchoscopy and invasive staging of mediastinal lymph nodes. Endobronchial ultrasound with transtracheal needle aspiration can be performed with real-time ultrasound guidance to facilitate transtracheal needle placement. Biopsies of other stations can be performed as well. If needed, cervical mediastinoscopy is performed with biopsy of high paratracheal (2R and 2L), low paratracheal (4R and 4L), pretracheal (3A), and subcarinal (7) lymph nodes. If left-sided aortopulmonary lymph nodes were FDG avid, a Chamberlain procedure (anterior mediastinotomy) or video-assisted thoracic surgery with biopsy of aortopulmonary window lymph nodes or hilar lymph nodes could also be performed. Additional evaluation of the patient would be warranted if the patient would be considered a surgical candidate.

characteristics. The staging system creates a shorthand description of the tumor, lymph nodes, and metastatic characteristics of the patient to facilitate the choice of optimal therapy and evaluate outcomes based on the clinical and pathologic stage. The American Joint Committee on Cancer (AJCC) and the Union for International Cancer Control work to establish and promulgate staging system guidelines. The 2018 8th edition TNM stage classification for lung cancer provides the basis for specific patient stage groupings and is used for initial treatment recommendations based on the clinical stage and on the pathologic stage after pulmonary resection.

The clinician's responsibility is to ensure the highest possible degree of certainty regarding the extent of the disease and recommend the therapy or therapeutic combination of greatest efficacy based on the disease stage. The clinical stage is the physician's best and final estimate of the extent of disease based on all available information from both invasive and noninvasive studies before the initiation of definitive therapy. Key noninvasive imaging modalities used in clinical staging of NSCLC patients are CT, PET/CT, and MRI of the brain. Invasive staging modalities are also often performed to complement and more accurately determine disease stage. This may include invasive mediastinal staging (endobronchial ultrasound [EBUS] or mediastinoscopy), pleural taps, and biopsies from suspected metastatic sites. The surgical pathologic stage is based on the clinical stage plus the physical extent of the disease based on histologic examination of resected tissues, including the hilar and mediastinal lymph nodes.

Current Lung Cancer 8th Edition Staging System

The International Association for the Study of Lung Cancer (IASLC), together with the AJCC, has recently issued the 8th edition of the lung cancer staging system based on data from ~95,000 patients diagnosed with lung cancer from 1999–2010. After exclusions, 70,967 with NSCLC and 6189 with SCLC were included in the analysis. Nearly 85% underwent surgical treatment, either alone (57.7%) or together with chemotherapy (21.1%), radiotherapy (1.5%), or both (4.4%). Survival was analyzed using Kaplan-Meier methods, and survival estimates were compared using the likelihood ratio test from Cox proportional hazards regression. Analysis allowed definition of TNM categories and stage groupings that demonstrated consistent discrimination overall and within multiple different patient cohorts (e.g., clinical or pathologic stage, R0 or R-any resection status, geographic region). Additional analyses provided evidence of applicability over time and across a spectrum of geographic regions, histologic types, evaluative approaches, and follow-up intervals.[22,23]

The 8th edition TNM definitions, nodal characteristics, and stage groupings of the TNM subsets are shown in Tables 110.1 to 110.3. Other schematics have been created for the lymph node map and T characteristics. The mediastinal and regional lymph node classification schema is presented in Fig. 110.11. This map presents a graphic representation of mediastinal and pulmonary lymph nodes in relation to other thoracic structures for optimal dissection and anatomic labeling by the surgeon.[24] The ninth edition staging system is forthcoming, with data collected from 2011–2019.

Tumor

The 8th edition of the IASLC/AJCC lung cancer staging project introduces, for the first time, special definitions for carcinoma in situ (Tis) and minimally invasive carcinomas (T1mis). Tis carcinomas are less than 3-cm noninvasive tumors that histologically display a pure lepidic growth pattern. T1mi tumors are smaller than 3 cm and histologically display a predominant lepidic growth pattern; however, they also have a small (<0.5-cm) invasive component. In addition, the definitions of the four classic lung cancer T categories (T1–T4) have also been refined. In the current edition, T1 tumors (<3 cm) are subcategorized as follows: T1a (<1 cm), T1b (1–2 cm), and T1c (2–3 cm). T2 tumors (>3–5 cm) are subcategorized as follows: T2a (3–4 cm) and T2b (4–5 cm). T3 tumors are 5 to 7 cm, and T4 tumors are >7 cm. T stage is also determined by extent of tumor involvement, outlined as follows:

- T2: Involvement of the main bronchus, invasion of the visceral pleural, or association with lobar/lung atelectasis are included.
- T3: Invasion of the parietal pleura, chest wall, phrenic nerve, parietal pericardium, or associated separate tumor nodule(s) in the same lobe as the primary tumor.
- T4: Invasion of the diaphragm, mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, carina, or separate tumor nodule(s) in a different ipsilateral lobe to that of the primary tumor.

Contrast-enhanced CT of the chest is the main imaging modality used to determine the T stage. MRI of the chest wall may assist in identifying chest wall involvement and in staging of superior sulcus tumors.

Lymph Nodes

The node descriptor (N0–N3) is defined according to the extent of lymph node metastasis along a predefined lymph node map with 14 lymph node stations. Station 10 to 14 nodes are confined to the lung, and metastasis to these nodes indicates N1 disease if ipsilateral to the tumor and N3 disease if contralateral to the tumor. Station 9 to 2 nodes are confined to the mediastinum, and metastasis to these nodes indicates N2 disease if ipsilateral to the tumor and N3 disease if contralateral to the tumor. Station 1 nodes are supraclavicular or suprasternal or low cervical nodes, and metastasis to these nodes indicates N3 disease.

The nodal characteristics and designations did not change in the 8th edition of the IASLC lung cancer staging project. However, a

TABLE 110.1 Tumor-Node-Metastasis (TNM) Descriptors for the 8th Edition of TNM Classification for Lung Cancer

T: Primary Tumor	
TX	Primary tumor cannot be assessed, or tumor proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor ≤3 cm in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e., not in the main bronchus)[a]
T1a(mi)	Minimally invasive adenocarcinoma[b]
T1a	Tumor ≤1 cm in greatest dimension[a]
T1b	Tumor >1 cm but ≤2 cm in greatest dimension[a]
T1c	Tumor >2 cm but ≤3 cm in greatest dimension[a]
T2	Tumor >3 cm **but ≤5 cm** or tumor with any of the following features[c]: • Involves main bronchus regardless of distance from the carina but without involvement of the carina • Invades visceral pleura • Associated with atelectasis or obstructive pneumonitis that extends to the hilar region, involving part or all of the lung
T2a	**Tumor >3 cm but ≤4 cm in greatest dimension**
T2b	**Tumor >4 cm but ≤5 cm in greatest dimension**
T3	**Tumor >5 cm but ≤7 cm in greatest dimension** or associated with separate tumor nodule(s) in the same lobe as the primary tumor or directly invades any of the following structures: chest wall (including the parietal pleura and superior sulcus tumors), phrenic nerve, parietal pericardium
T4	**Tumor >7 cm in greatest dimension** or associated with separate tumor nodule(s) in a different ipsilateral lobe than that of the primary tumor or invades any of the following structures: diaphragm, mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, and carina
N: Regional Lymph Nodes Involvement	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
M (Distant Metastasis)	
M0	No distant metastasis
M1	Distant metastasis present
• M1a	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural or pericardial nodule(s) or
• M1b	malignant pleural or pericardial effusion[d]
• M1c	Single extrathoracic metastasis[e]
	Multiple extrathoracic metastases in one or more organs

Note: Changes from the seventh edition are in bold.

[a] The uncommon superficial spreading tumor of any size with its invasive component limited to the bronchial wall, which may extend proximal to the main bronchus, is also classified as T1a.

[b] Solitary adenocarcinoma, ≤3 cm with a predominately lepidic pattern and ≤5-mm invasion in any one focus.

[c] T2 tumors with these features are classified as T2a if ≤4 cm in greatest dimension or if size cannot be determined and as T2b if >4 cm but ≤5 cm in greatest dimension.

[d] Most pleural (pericardial) effusions with lung cancer are a result of tumor. In a few patients, however, multiple microscopic examinations of pleural (pericardial) fluid are negative for tumor, and the fluid is nonbloody and not an exudate. When these elements and clinical judgment dictate that the effusion is not related to the tumor, the effusion should be excluded as a staging descriptor.

[e] This includes involvement of a single distant (nonregional) lymph node.

From Goldstraw P, Chansky K, Crowley J, et al. The IASLC lung cancer staging project: proposals for revision of the TNM stage groupings in the forthcoming (eighth) edition of the TNM classification for lung cancer. *J Thorac Oncol.* 2016;11:39-51.

recommendation is made to define nodal involvement not only by the N0–N3 descriptors but also by quantifying the number of involved lymph nodes. In particular, nodal quantification by the number of involved nodal stations is defined as follows: N1a, single N1 nodal station; N1b, multiple N1 nodal stations; N2a1, single N2 nodal station without N1 involvement (skip metastasis); N2a2, single N2 nodal station with N1 involvement; and N2b, multiple N2 nodal stations.

Prognosis worsens as the number of involved nodal stations increases, but N1b and N2a1 have the same prognosis. Asamura and colleagues[25] demonstrated different 5-year survival rates according to nodal stage for patients who underwent complete resection: N1a (59% 5-year survival), N1b (50%), N2a1 (54%), N2a2 (43%), and N2b (38%).

FDG/PET combined with contrast-enhanced CT is the main imaging modality used to determine the N stage. Hilar and mediastinal nodes that are suspected to be involved by cancer (>1 cm) or have positive FDG uptake are typically biopsied to confirm tumor metastasis.

Metastases

The 8th edition of lung cancer staging defines two M descriptors, M0 and M1, with M1 being subcategorized into M1a, M1b, and M1c. **M1a** indicates endothoracic metastasis (malignant pleural/pericardial effusion or malignant pleural/pericardial nodules or separate tumor nodule in a contralateral lobe). **M1b** indicates the presence of a single extrathoracic metastasis in a single organ. **M1c** indicates the presence of multiple extrathoracic metastases in a single organ or in multiple organs. Although M1a and M1b tumors have similar prognosis, they represent different forms of metastatic involvement and require different diagnostics and therapeutics. FDG/PET combined with contrast-enhanced CT is the main imaging modality used to determine the M stage. Brain MRI is used to identify brain metastasis. Suspected metastatic lesions may be biopsied to confirm diagnosis or determine treatment plan. Otherwise, metastatic lesions are not routinely sampled.

LYMPH NODE STATION NO.	ANATOMIC LIMITS
4: Lower paratracheal nodes	• 4R: Includes right paratracheal nodes and pretracheal nodes extending to the left lateral border of the trachea • Upper border: Intersection of caudal margin of innominate vein with the trachea • Lower border: Lower border of the azygos vein • 4L: Includes nodes to the left of the left lateral border of the trachea, medial to the ligamentum arteriosum • Upper border: Upper margin of the aortic arch • Lower border: Upper rim of the left main pulmonary artery
Aortopulmonary Zone	
5: Subaortic (aortopulmonary window)	• Subaortic lymph nodes lateral to the ligamentum arteriosum • Upper border: The lower border of the aortic arch • Lower border: Upper rim of the left main pulmonary artery
6: Para-aortic nodes (ascending aorta or phrenic)	• Lymph nodes anterior and lateral to the ascending aorta and aortic arch • Upper border: A line tangential to the upper border of the aortic arch • Lower border: The lower border of the aortic arch
Subcarinal Zone	
7: Subcarinal nodes	• Upper border: The carina of the trachea • Lower border: The upper border of the lower lobe bronchus on the left; the lower border of the bronchus intermedius on the right
Lower Zone	
8: Paraesophageal nodes (below carina)	• Nodes lying adjacent to the wall of the esophagus and to the right or the left of the midline, excluding subcarinal nodes • Upper border: The upper border of the lower lobe bronchus on the left; the lower border of the bronchus intermedius on the right • Lower border: The diaphragm
9: Pulmonary ligament nodes	• Nodes lying within the pulmonary ligament • Upper border: The inferior pulmonary vein • Lower border: The diaphragm
Hilar/Interlobar Zone	
10: Hilar nodes	• Includes nodes immediately adjacent to the mainstem bronchus and hilar vessels, including the proximal portions of the pulmonary veins and main pulmonary artery • Upper border: The lower rim of the azygos vein in the right, upper rim of the pulmonary artery on the left • Lower border: Interlobar region bilaterally

11: Interlobar nodes	• Between the origins of the lobar bronchi
	• Optional notations for subcategories of station:
	  • 11s: Between the upper-lobe bronchus and bronchus intermedius on the right
	  • 11i: Between the middle and lower bronchi on the right

Peripheral Zone	
12: Lobar nodes	Adjacent to the lobar bronchi
13: Segmental nodes	Adjacent to the segmental bronchi
14: Subsegmental nodes	Adjacent to the subsegmental bronchi

Adapted from Rusch VW, Asamura H, Watanabe H, et al. The IASLC lung cancer staging project: a proposal for a new international lymph node map in the forthcoming seventh edition of the TNM classification for lung cancer. *J Thorac Oncol.* 2009;4:568-577.

Stages

The 8th edition of the lung cancer staging system has refined and expanded the lung cancer stage definitions to produce a more precise tool to predict prognosis and guide treatment plan (Fig. 110.12). Pretreatment staging determines prognosis: 5-year survival rates by *pathologic* stage are 90% for stage IA1, 85% for stage IA2, 80% for stage IA3, 73% for stage IB, 65% for stage IIA, 56% for stage IIB, 41% for stage IIIA, 24% for stage IIIB, and 12% for stage IIIB. For *clinical* stage, the 5-year survival rates by clinical stage are 13% for stage IVA and nearly 0% for stage IVB.

Treatments for Lung Cancer

The choice of initial therapy depends on the clinical stage at the time of diagnosis and the patient's functional class and comorbidities. Treatment options may vary, even among different subsets of patients within the same clinical stage. Broadly, lung carcinoma should be resected when the local disease can be controlled, the patient's physical condition can tolerate the planned resection and reconstruction, and the anticipated operative morbidity and mortality are reasonable. Conditions such as superior vena cava syndrome, tumor invasion across the mediastinum into the main pulmonary artery, N3 nodal metastases, malignant pleural or pericardial disease, or extrathoracic metastases carry greater risk than benefit for resection in most patients. Some centers have had good results with resection and reconstruction of the trachea, atrium, great vessels, or other mediastinal or vertebral structures. However, these are complex operations requiring experienced multidisciplinary teams during the pre-, intra-, and postoperative phases. Patients with tracheoesophageal fistula have a limited life expectancy, and palliative care with stent placement would be recommended.

Treatments can be grouped into three major categories according to stage, as follows:

1. Stage I and II disease indicate the presence of tumor that is contained within the lung and that may be completely resected with surgery. Anatomic resection of the lobe where the tumor resides with complete sampling of mediastinal lymph nodes is the treatment of choice. The key aim of this treatment approach is to achieve complete resection of the tumor and its intralobar-draining lymph nodes. In certain cases, sublobar anatomic resections may be considered for small and peripheral tumors. There is a growing body of evidence to suggest sublobar resections are at least not inferior to anatomic resection.[26,27] However, anatomic resection remains the standard of care, and nonanatomic resection should be performed only when more extensive surgery cannot be tolerated by the patient (e.g., because of reduced pulmonary reserve). Stereotactic body radiation therapy (SBRT) has had excellent results (local control rates of 85%–90% at 3 years) in selected patients who cannot withstand surgical resection[28] and even as an alternative to operable tumors in some patient groups.[29]
2. Stage IV and IIIB disease are not typically treated by surgery except in patients requiring surgical palliation. Systemic therapies for metastatic disease are common. Chemoradiation is often used in stage IIIB disease. Targeted therapies and immunotherapy are providing encouraging results in properly screened and selected patients. Figs. 110.13 and 110.14 outline current molecular therapeutic targets.
3. Stage IIIA lung cancer indicates a locally advanced disease that may have a wide spectrum of presentations. The majority of stage IIIA tumors are too advanced for consideration of resection; however, if complete resection is deemed possible, it may be associated with improved outcomes. In this clinical scenario, surgical resection is performed as part of a multimodality treatment protocol. In particular, resectable stage IIIA tumors are either small tumors that present with a low metastatic burden to the ipsilateral mediastinal (N2) lymph nodes or larger tumors that do not involve mediastinal lymph nodes (T4N0/1M0). These tumors, by their advanced nature, may be mechanically removed with surgery; however, surgery does not consistently control the micrometastases that exist within the general area of the operation or systemically. Combinations of chemotherapy and radiotherapy, and in recent years also immunotherapy, are used for locally advanced disease either in the adjuvant or neoadjuvant settings.[30–32] A multidisciplinary team of experts usually predefines the desired treatment plan in each case.

Local Therapy for Early Stage Non–Small Cell Lung Cancer

Stages I and II NSCLC can be treated safely with surgery and mediastinal lymph node dissection, and most patients have long-term survival. Stage Ia and Ib tumors should be treated with surgery first, followed by adjuvant systemic chemotherapy for tumors with high-risk features. Stage II tumors should be treated with

systemic therapy followed by surgical resection. There is a growing body of evidence to support the use of perioperative systemic immunotherapy in combination with chemotherapy in these patients.[31,32] Anatomic resection with lobectomy and systematic mediastinal lymph node dissection or sampling (defined by the American College of Surgeons Oncology Group) is the procedure of choice for lung cancer confined to one lobe. Sublobar resection may be considered in select groups, including patients with small peripheral tumors or those who cannot tolerate an anatomic lobectomy. Recent randomized control trials have demonstrated at least noninferiority of sublobar resection compared with lobectomy in a more generalized patient group.[26,27] At a minimum, samples of nodal (not adipose) tissue from stations 4R, 7, 8, and 9 for right-sided cancers and stations 4L, 5, 6, 7, 8, and 9 for left-sided cancers should be obtained.

Treatment of Metastatic Disease

Metastatic disease (stage IV NSCLC) is usually incurable. Patients and families should be informed of the diagnosis and potential outcomes of treatment, including the reality that functional performance and quality of life will progressively decline. Treatment decisions should take into consideration the wishes of the patient and family, and realistic expectations should be set and monitored during therapy. In recent years, a growing number of biologic and immunologic therapies have been approved for the treatment of advanced NSCLC. In combination with conventional chemotherapy and radiation, these new therapeutics have significantly expanded the therapeutic options for patients with advanced inoperable NSCLC (stages IV and IIIB).

TRACHEA

The major physiologic role of the trachea is to conduct air between the larynx and the bronchi, exchange heat and moisture, and remove particles. The transport of air is dependent on the inner diameter of the trachea. Mucosal swelling, constriction of airway muscles, or tumors that reduce the airway space, but also endotracheal tubes, considerably increase the resistance to airflow: A 50% reduction of the inner diameter increases the resistance 16-fold, and during turbulent flow, the resistance is increased up to 32-fold. During inspiration, the upper airways efficiently warm and humidify the inspired air. During quiet breathing at room temperature, air is completely warmed up to 37°C and humidified to 100% saturation shortly distal to the bifurcation; this is called the *isothermal saturation point.* Tracheobronchial glands produce a mucin-rich secretion that forms a protective barrier between the epithelium and the environment. This secretion is largely controlled by the autonomic nervous system. The mucus collects debris and microorganisms and is transported orally by the mechanical forces of coordinated ciliary beating and the airflow during expiration.[33]

Benign Stenosis of the Trachea

Stenosis of the trachea describes a narrowing of the tracheal lumen and typically implies significant functional impairment. A normal 2-cm trachea has a 100% peak expiratory flow rate. A 10-mm opening provides an 80% peak expiratory flow rate. At 5 to 6 mm, only a 30% expiratory flow rate is obtained. Benign stenosis of the trachea results mainly from tracheotomy, overinflation of the endotracheal tube cuff during mechanical ventilation, or external trauma, but it is also associated with inhalation/thermal injury, autoimmune diseases, infection (commonly tuberculosis), and nonmalignant tumors. Tracheotomy leads to a transmural defect of the ventral part of the cervical trachea. The tracheotomy wound is colonized by bacteria, with local necrosis by mechanical alteration. After removal of the tracheostomy tube, the defect is closed by the secondary scar tissue healing, which tends to contract. This process of healing results in an A-shaped stenosis of the trachea (Fig. 110.15). The severity of shrinkage depends on the extension of the defect, necrosis, and infection. Low-volume, high-pressure cuffs of ventilation tubes induce circular necrosis of the tracheal mucosa. Depending on the pressure, the duration of ischemia, and local infection, the underlying cartilages may be bare, necrotic, and destroyed. A cuff pressure over 20 cm H_2O can exceed capillary perfusion pressure. Remember that the proper amount of air in an endotracheal tube cuff is the minimal amount to prevent an air leak. Mucosal defects without infection can be recovered from surrounding epithelium without relevant morbidity. Deeper destruction and infection of the tracheal wall leads to a ring of granulation tissue, forming a sandglass stenosis. Cuff-induced stenosis appears in the middle part of the trachea. The introduction of low-pressure, high-volume cuffs has made this kind of tracheal stenosis much rarer.[34]

Symptoms of tracheal obstruction can occur immediately after extubation or slowly over several years. Clinical signs like stridor

FIGURE 110.13 Alterations in targetable oncogenic pathways in lung adenocarcinoma (LUAD) and lung squamous cell carcinoma (LUSC). Pathway diagram showing the percentage of non–small cell lung cancer with alterations involving key pathway components for receptor tyrosine kinase signaling, mammalian target of rapamycin *(mTOR)* signaling, oxidative stress response, proliferation, and cell cycle progression. The frequency of alterations is based on the sum of somatic mutations, homozygous deletions, and focal amplifications and on significant up- or downregulation of gene expression (e.g., *AKT3, FGFR1, PTEN*). The most commonly mutated genes in LUAD include *KRAS* and *EGFR* and the tumor-suppressor genes *TP53, KEAP1, STK11,* and *NF1*. The frequency of epidermal growth factor receptor (EGFR)-activating mutations varies greatly by region and ethnicity. *KEAP1* inactivation in the presence of *KRAS* mutations confers sensitivity to inhibition of glutaminase in preclinical lung cancer models, providing a potential therapeutic strategy in dual *KEAP1*- and *KRAS*-mutant LUAD. Common mutated genes in LUSC include the tumor suppressors *TP53,* which is present in more than 90% of tumors, and *CDKN2A*. The latter, which encodes the p16INK4A and p14ARF proteins, is inactivated in over 70% of LUSC through epigenetic silencing by methylation (21%), inactivating mutation (18%), exon 1β skipping (4%), or homozygous deletion (29%). Although EGFR amplification occurs, unlike LUAD, actionable mutations in receptor tyrosine kinases are rarely observed in LUSC. (From Herbst RS, Morgensztern D, Boshoff C. The biology and management of non-small cell lung cancer. *Nature.* 2018;553:446-454.)

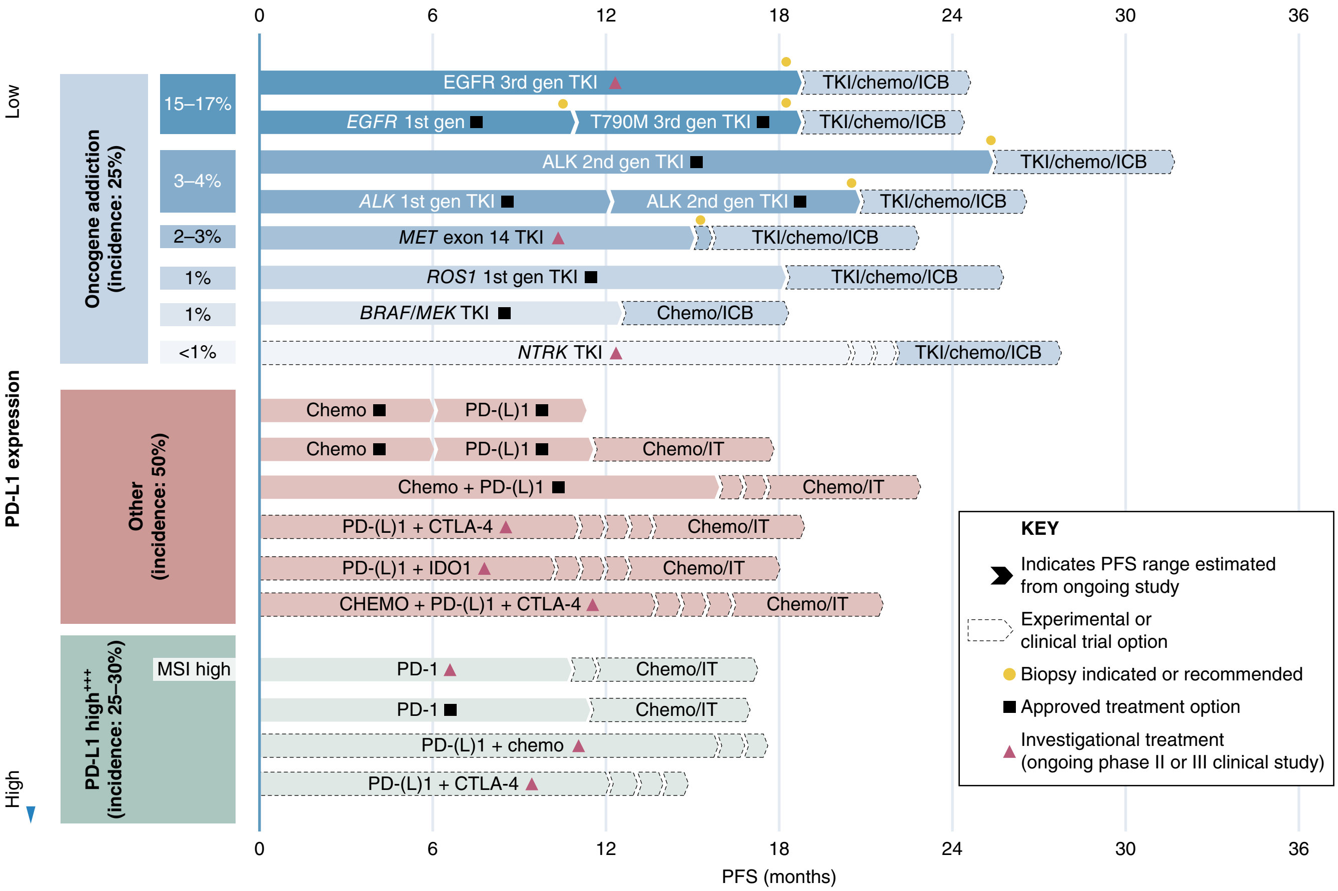

FIGURE 110.14 Current and investigative treatment options for advanced or metastatic non–small cell lung cancer (NSCLC). Illustration of the current and future personalized treatment options for NSCLC. Targetable oncogenic drivers account for approximately 25% of NSCLC, of which epidermal growth factor receptor mutations are the most frequent. Biopsies are indicated at the time of disease progression to determine the best treatment option. For patients with tumors expressing high levels of programmed cell death ligand 1 *(PD-L1)* (>50%) or high levels of microsatellite instability *(MSI),* single-agent immune checkpoint blockade *(ICB)* is indicated. In general, median progression-free survival is not the best indicator to capture the overall true benefit of ICBs because a proportion of patients remain alive or disease-free even after long-term follow-up. In patients with tumors with high (>50%) or low (>1%) expression levels of PD-L1, current studies are assessing the benefit of anti–PD-(L)1 combinations with cytotoxic therapy, anti–cytotoxic T-lymphocyte–associated protein 4, or other immunotherapy approaches. *TKI,* Tyrosine kinase inhibitor. (From Herbst RS, Morgensztern D, Boshoff C. The biology and management of non-small cell lung cancer. *Nature.* 2018;553:446-454.)

and dyspnea appear when the lumen is obliterated by more than 50%; however, clinical signs and lung function testing are not very sensitive or specific for tracheal stenosis. Standard of treatment for symptomatic patients consists of resection of the pathologic segment of the trachea with end-to-end anastomosis. In cases of involvement of the larynx, partial resections of the anterior cricoid cartilage or division of the larynx with tracheolaryngeal silicone stents is used. Short- and long-term results are satisfying.

Primary Neoplasm of the Trachea

Most tumors of the trachea in adult patients are malignant, and although primary tumors do occur, they most commonly represent direct invasion of the trachea from carcinoma of the surrounding structures (lung, esophagus, larynx, or thyroid gland). Hematogenous tracheal metastases have also been described in patients with carcinoma of the breast, colon, and kidney and melanoma skin lesions.[35] For all tracheal tumors, primary or otherwise, the most common presenting symptoms are due to mass effect; frequently symptoms do not arise until the tumor obstructs ≥50% of the luminal diameter, and presentation varies based on the location of the tumor and histologic subtype.

The most common primary tracheal tumor is SCC, which comprises approximately one-half to two-thirds of cases. Up to 10% can be multifocal. Tumors may arise as an intraluminal nodule and progress to include mediastinal extension or lymph node metastases and may lead to stenosis or tracheoesophageal fistula. They are histologically identical to SCCs of the lung. SCCs often present with hemoptysis, given mucosal irritation and ulceration, and are typically diagnosed within 4 to 6 months of symptom onset. Dysphagia and hoarseness may also be present. The peak incidence is in the sixth to seventh decade of life. These tumors are seen primarily in smokers.

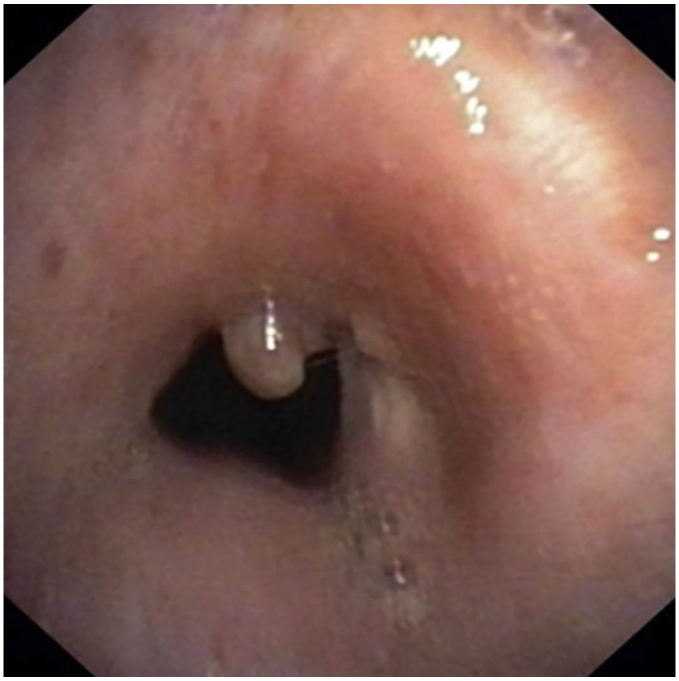

FIGURE 110.15 Tracheoscopy 3 months after decannulation with stenosis of the trachea by shrinkage and granulation tissue. (From Stoelben E, Koryllos A, Beckers F, et al. Benign stenosis of the trachea. *Thorac Surg Clin.* 2014;24:59-65.)

The next most common primary tracheal tumor (accounting for 10%–15% of cases) is adenoid cystic carcinomas (ACCs), previously called *cylindroma*. These are well-differentiated, slow-growing neoplasms that typically form polypoid lesions in the trachea or main stem bronchi, but they may form infiltrative plaques with longitudinal or circumferential extension and often breach the cartilaginous plate. Perineural invasion and extension along vascular structures is very common and accounts for the high rate of positive surgical margins, well beyond the gross limits of the tumor. ACCs can have multiple recurrences with late metastases. They are histologically identical to ACCs of the salivary glands. ACC commonly presents with wheezing or exertional dyspnea, with hemoptysis present in only a minority of cases. Diagnosis is established on average 18 months after symptom presentation. The peak incidence occurs in the fourth and fifth decades of life. It affects males and females equally and usually affects nonsmokers.[36]

Less common primary tracheal tumors include mucoepidermoid carcinoma, non–squamous cell bronchogenic carcinomas, sarcomas, carcinoid tumors, and pleomorphic adenoma. Benign tracheal lesions include hemangioma, hamartoma, neurogenic tumors, granular cell tumor, and squamous papillomas. Low-grade tumors, such as mucoepidermoid carcinomas or benign tumors, may be asymptomatic for years before diagnosis.

The diagnosis of tracheal tumors is often delayed as a result of similar presenting symptoms with other etiologies, including asthma, COPD, and pneumonia. Chest CT is recommended for patients in whom a tracheal pathology is suspected. This study may reveal polypoid lesions, focal stenosis, eccentric narrowing, or circumferential wall thickening. Bronchoscopy is mandatory to obtain a tissue diagnosis and differentiate between benign and malignant tumors. PET/CT may be useful for staging the cancer, but data on tracheal tumors are limited. Preoperative PET/CT scans may help to assess extent of disease and resectability, particularly for SCC.

There is no standardized staging system for tracheal tumors. The primary treatment modalities are surgery and radiation therapy. The outcome of treatment depends on the stage and histology. There are no prospective or randomized trials directing the most efficacious treatment approach. Whenever possible, complete surgical resection is the treatment of choice for malignant tracheal tumors, given retrospective data suggesting improved disease outcomes and acceptable postoperative morbidity. The suggested maximum resected length of trachea is 5 cm because there is no suitable replacement material. Available data suggest that postoperative radiotherapy improves survival for patients with incompletely resected squamous SCC and ACC but not for those with completely resected tumors. For patients with unresectable, nonmetastatic SCC or ACC, concurrent chemoradiotherapy with a platinum-based regimen may be attempted, although data are limited.[37]

Involvement of the trachea as a result of local extension from bronchogenic carcinoma may contraindicate resection. Involvement of the trachea as a result of local extension of esophageal carcinoma may require palliative therapy or stent placement.

Tracheal Trauma

The trachea is anatomically protected from injury by the bony sternum, rib cage, and vertebral column. When blunt or penetrating injuries of the tracheobronchial tree do occur, they are often accompanied by a variety of potentially life-threatening injuries. Penetrating tracheobronchial injuries are more common than blunt injuries and are most commonly caused by gunshot wounds. The most common site of penetrating injuries is the cervical trachea, likely reflecting a high rate of mortality for anatomically lower injuries. Major associated injuries, mainly of the esophagus and great vessels, have been reported in 50% to 80% of penetrating injuries. Blunt tracheobronchial injuries are associated with major accompanying injuries in 40% to 100% of cases, commonly including pneumothorax/hemothorax, rib fractures, pulmonary contusion, laryngeal fracture, esophageal injury, cervical spine, and great vessel injuries.[38]

The most common clinical signs of tracheal injury are tachypnea and subcutaneous emphysema. Other signs include air escaping from the neck wound, massive air leak after placement of a tube thoracostomy, hemoptysis, stridor, and dysphagia. CXR and chest CT are the first steps in diagnosis. Paratracheal air, deep cervical emphysema, and pneumomediastinum are common findings. Bronchoscopy is the most important procedure to locate and assess trachea-bronchial injuries. Early airway assessment followed by definitive airway protection is the key to neck trauma management and trachea-bronchial injuries. Concurrent esophageal injury needs to be excluded by barium esophagography or esophagoscopy. Anesthetic management with laryngeal mask airway may be helpful for initial examination for full visualization of the airway before endotracheal intubation.

Nonoperative management with close monitoring may be considered for patients with blunt trauma and small stable injuries, those with no appreciable air leaks, and those who do not require positive pressure ventilation. For all other cases, immediate exploration of neck wounds is crucial for survival because vascular and esophageal injuries are frequent, and the tracheal injury often includes cartilage and ligamentous portions. Primary surgical repair represents the treatment of choice to reestablish airway continuity. Bronchial disruption may require thoracotomy for repair. Right thoracotomy provides excellent visualization of the carina and proximal left mainstem bronchus.

Acquired tracheoesophageal fistula can occur from cancer or from prolonged intubation with erosion posteriorly. Repair is with separation of the trachea and esophagus; repair of the fistulous tract; and interposition of normal tissue, such as muscle, between the two structures.

Tracheoinnominate fistula may result from prolonged cuff erosion inferiorly and anteriorly in the trachea. An inappropriately low stoma may further increase the likelihood of a direct erosion of the trachea by the innominate artery. The tip of the endotracheal tube may predispose to erosions or granulomas within the trachea. Tracheoinnominate fistula may manifest with a sentinel hemorrhage before sudden exsanguinating hemorrhage. Investigation of these sentinel hemorrhage episodes is critical. Evaluation in the operating room may provide for optimal situational control should additional interventions be required.

Principles of Tracheal Surgery

Elective or emergent tracheal surgical procedures are typically performed to improve tracheal patency or repair loss of tracheal integrity. Anesthetic challenges include abnormal airway anatomy and physiology, specialized endotracheal tubes for initial airway management, and evolving ventilatory challenges if the trachea is open or obstructed intraoperatively.

General inhalational anesthesia is used, and induction may be prolonged in the setting of tight stenosis. The patient should be maintained with spontaneous breathing if possible. Dilation with rigid bronchoscopy may be required before passing the endotracheal tube, especially if the stenosis is subglottic. Alternatively, the endotracheal tube may be positioned to a point above the stricture for induction.

Surgical approach is determined by tumor location and pathology. The cervical approach for tracheal resection is usually used for tumors of the upper half of the trachea plus all benign tracheal stenoses. Occasionally, an upper sternal split may be needed (Fig. 110.16). For tumors of the lower trachea, resection is performed in the right fourth intercostal space with intubation of the distal trachea or the left main stem bronchus. Carinal reconstruction may be necessary. Rigid bronchoscopy may be used for diagnosis, biopsy, dilation, or morcellation of tumor if the tumor cannot be immediately resected (Fig. 110.17).

Conventional teaching advises resection of no more than 5 cm of tracheal length, but this varies from person to person. Various

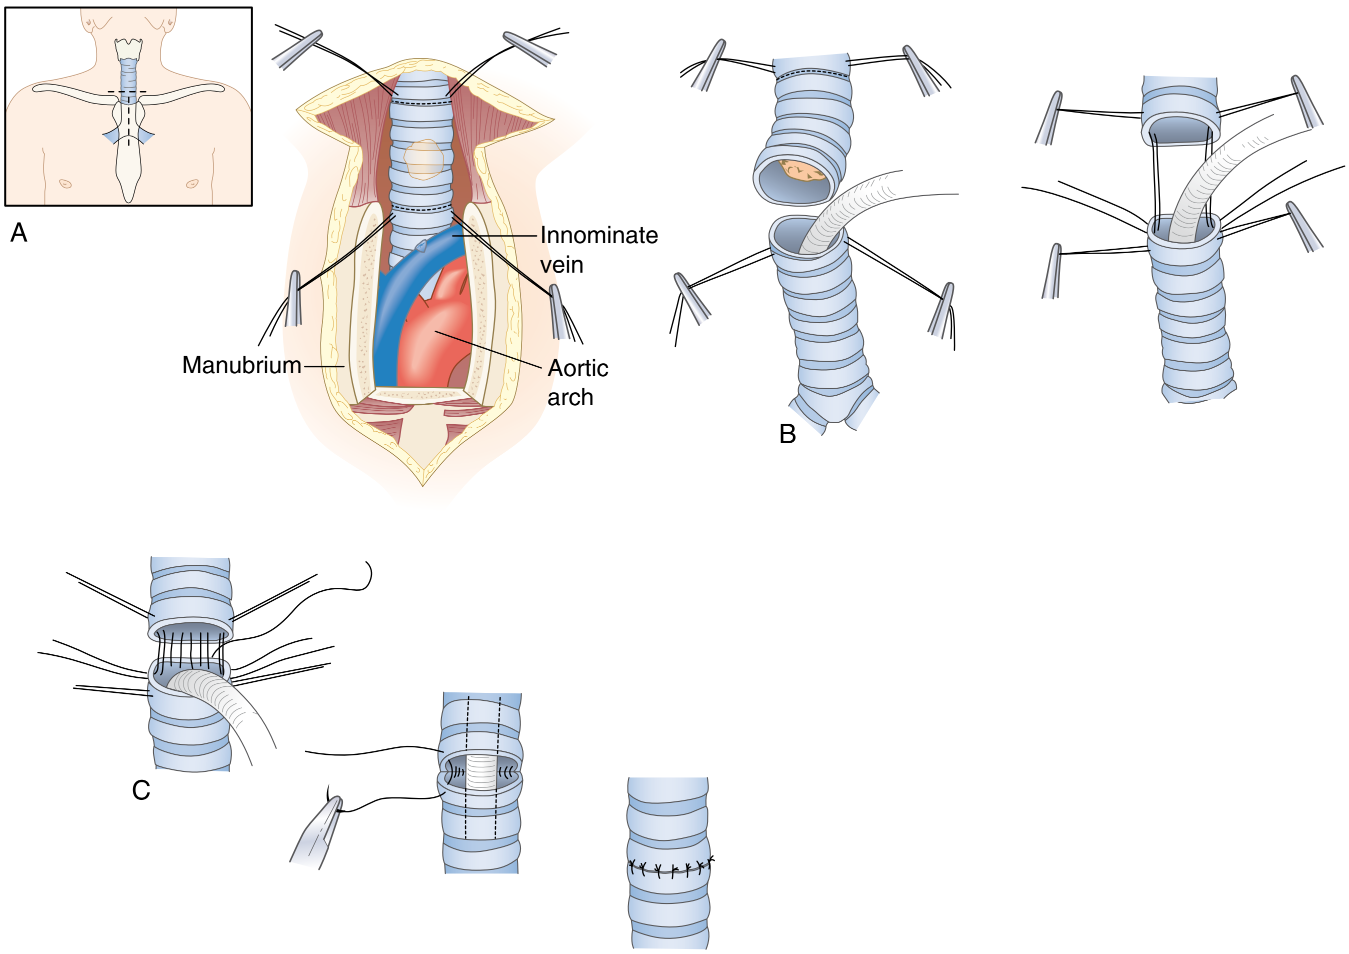

FIGURE 110.16 (A) Exposure of the midtrachea through a cervical and partial sternal-splitting incision. The extent of the resection has been marked by sutures. (B) After distal division, a sterile, armored endotracheal tube is placed. After proximal resection, two mattress sutures are placed in the edges of the cartilaginous rings. A simple running suture completes the membranous anastomosis. (C) At this point, the original endotracheal tube is positioned in the distal trachea so that the anastomosis can be completed with interrupted simple sutures between cartilaginous rings.

FIGURE 110.17 (A) Proper technique for rigid bronchoscopy in a patient with a tracheal mass. *Top,* Pharyngeal packing used to protect the esophagus is shown. The surgeon should be cautious because this packing can move and may obstruct the larynx. Complete removal of the packing is done at the end of the operation. *Middle,* A nearly obstructing tumor is shown. *Bottom,* A flexible bronchoscope is placed into the rigid scope for the biopsy. This protects the airway. (B) Technique for endoscopic resection of a tracheal mass with a rigid bronchoscope without *(top)* and with *(bottom)* use of the laser. (From Sugarbaker DJ, Mentzer SJ, Strauss G, et al. Laser resection of endobronchial lesions: use of the rigid and flexible bronchoscopes. *Oper Tech Otolaryngol Head Neck Surg.* 1992;3:93.)

techniques are used to mobilize the trachea to create a repair without undue tension on the anastomosis. The anterior cervical approach plus mobilization of the trachea and neck flexion can allow for 4 to 5 cm of trachea resection. A suprahyoid release may achieve 1 cm of additional length. Mobilization of the right hilum, together with division of the pericardium around the right hilum, may achieve an additional length.[39]

Procedures to repair subglottic larynx or cricoid stenosis are technically challenging. The recurrent nerves innervate the larynx just superior to the posterolateral cricoid on each side. If the tracheal lesions involve only the anterior surface, the anterior cricoid can be removed and the distal trachea beveled to match the defect; this maneuver spares the recurrent laryngeal nerves. With circumferential involvement, it may be necessary to perform a laryngectomy.

Contraindications to trachea repair include (1) inadequately treated laryngeal problem (not including paralysis of a single vocal cord); (2) need for ventilatory support or permanent tracheostomy for patients with amyotrophic lateral sclerosis, myasthenia gravis, or quadriplegia; (3) use of high-dose steroids; and (4) inflamed or recent tracheostomy. Poor pulmonary reserve is not a contraindication for repair in patients who have been weaned from the ventilator.

PULMONARY INFECTIONS

Pulmonary infections requiring surgical interventions are infrequent compared with pleural space infections. Clinical features resemble pneumonia and include fever, cough, leukocytosis, pleuritic pain, and sputum production. The patient is specifically questioned about aspiration of a foreign body. Evaluation includes CXR and CT scan of the chest and upper abdomen. Bronchoscopy can be performed to clear secretions and/or biopsy when cancer, foreign body, bronchial stenosis, or stricture are suspected. Cultures may be obtained to facilitate antibiotic treatment. Medical treatment must be optimized and may include smoking cessation, postural drainage, bronchodilator medications, and antibiotics.

Bronchiectasis

Bronchiectasis is a chronic respiratory disease characterized radiologically by abnormal and permanent dilation of the bronchi. Clinically, it can resemble COPD and is characterized by cough, sputum production, and bronchial infection. Pathophysiologically, two inciting factors are required: (1) an infectious insult and (2) impaired drainage, airway obstruction, or diminished host immune function. There are numerous predisposing factors, including CF, α_1-antitrypsin deficiency, primary ciliary syndrome (Kartagener syndrome), bronchial obstruction from foreign body, extrinsic lymph nodes that compress the bronchus, neoplasm, or mucus plug (Fig. 110.18).

Exacerbations of bronchiectasis are associated with increased airway and systemic inflammation and progressive lung damage that can lead to pulmonary functional decline and respiratory failure. Chronic airway infection stimulates and sustains pulmonary inflammation that is primarily neutrophilic and leads to degradation of airway elastin, with associated bronchial dilation, bronchial wall thickening, and mucus plugging. Common pathogens include *Haemophilus influenzae* and *Pseudomonas aeruginosa;* less frequent pathogens include *Moraxella catarrhalis, Staphylococcus aureus,* and *Enterobacteriaceae.* Mucociliary clearance is impaired by the impact of structural bronchiectasis, airway dehydration, excess mucus volume, and viscosity. More than 50% of patients have airflow obstruction, but a restrictive, mixed ventilatory pattern and preserved lung function are also frequently observed.

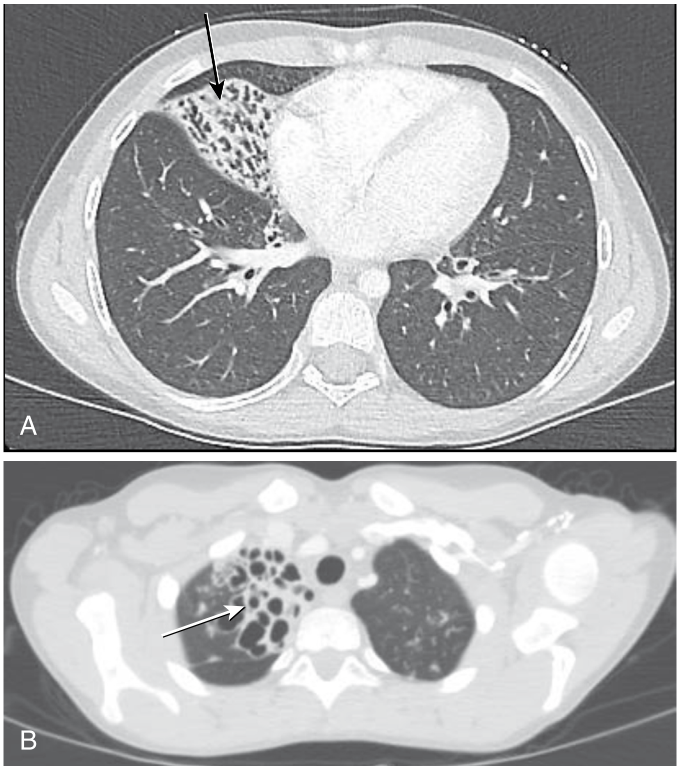

FIGURE 110.18 (A) A chest computed tomography (CT) scan of an 8-year-old patient with primary ciliary dyskinesia shows severe bronchiectasis of the right middle lobe *(arrow).* (B) A chest CT scan of a 6-year-old patient with cystic fibrosis shows severe bronchiectasis of the right upper lobe *(arrow).*

Treatment is based on the principles of preventing or suppressing acute and chronic bronchial infection, improving mucociliary clearance, and reducing the impact of structural lung disease. Therapies may include bronchodilator medications, pulmonary rehabilitation, or surgical resection. Surgery is considered for patients with localized disease and a high burden of exacerbations despite optimal medical management. The rationale for surgical resection (typically with lobectomy) is to break the self-sustaining inflammatory cycle of bronchiectasis by removing the involved lung segments to prevent spread to adjacent lung zones. Surgery may also be indicated in patients who develop massive hemoptysis refractory to bronchial artery embolization. Minimally invasive approaches are often preferred over open resection because VATS has been reported to produce comparable symptomatic improvement with shorter hospital stay, fewer complications, and less pain.[40] Bilateral bronchiectasis is a relative contraindication for surgery. For these patients, consider prolonged conservative treatment or bronchial artery embolization.

Lung Abscess

Lung abscess is defined as a circumscribed area of pus or necrosis caused by microbial infection and contained within the pulmonary parenchyma. Most lung abscesses arise as a complication of aspiration and are caused by species of anaerobes that are normally present in the gingival crevices. They are typically polymicrobial, and the most common organisms are *Peptostreptococcus,* *Prevotella, Bacteroides* (usually not *B. fragilis*), and *Fusobacterium* spp. Many other bacteria can also cause lung abscesses, including *Streptococcus anginosus, S. aureus, K. pneumoniae, Streptococcus pyogenes, Burkholderia pseudomallei, Haemophilus influenzae* type b, *Legionella, Nocardia,* and *Actinomyces.* In the immunocompromised host, the most common causes of lung abscess are *P. aeruginosa* and other aerobic gram-negative bacilli, *Nocardia* spp., and fungi (*Aspergillus* and *Cryptococcus* spp.).

Most patients with lung abscesses (including nearly all of those caused by anaerobic infections) present with indolent symptoms that mimic pneumonia and evolve over a period of weeks or months. The characteristic features suggest pulmonary infection, including fever, cough, and sputum production. Evidence of chronic systemic disease is usually present, with night sweats, weight loss, and anemia.

A chest radiograph will often demonstrate infiltrates with a fluid-filled cavity, frequently in a segment of the lung that is dependent in the recumbent position (e.g., the superior segment of a lower lobe or a posterior segment of the upper lobes). A better anatomic definition can be achieved with CT. It can be particularly helpful if there is a question of cavitation that cannot be clearly delineated on the chest radiograph or if an associated mass lesion is suspected. CT will also distinguish between a parenchymal lesion and a pleural collection, which are managed very differently (Fig. 110.19).

The antibiotic treatment of lung abscess is almost always empiric, typically with IV ampicillin-sulbactam but with alternatives for special patient groups. Empiric regimens should penetrate the lung parenchyma and target both strict anaerobes and facultatively anaerobic streptococci. Drugs that are reasonable to use are any combination of a β-lactam–β-lactamase inhibitor or a carbapenem. The duration of therapy is controversial. Some treat for three weeks as a standard, and others treat based on the response.

Bronchoscopy may be used for treatment to assist in drainage of the cavity either directly or via transbronchial catheterization. Most patients (85%–95%) respond to medical management with a rapid decrease in fluid, collapse of the walls, and complete healing in 3 to 4 months. Patients with symptoms for longer than 3 months before treatment or cavities larger than 4 to 6 cm are less likely to respond to medical management and may require surgery.

Surgical therapy is indicated for persistent cavity (≥2 cm and thick walled), failure to clear sepsis after 8 weeks of medical therapy, hemoptysis, and exclusion of cancer. Lobectomy is typically required. If a lung abscess ruptures into the pleural cavity, simple drainage may suffice, and the patient is managed for empyema or bronchopleural fistula.

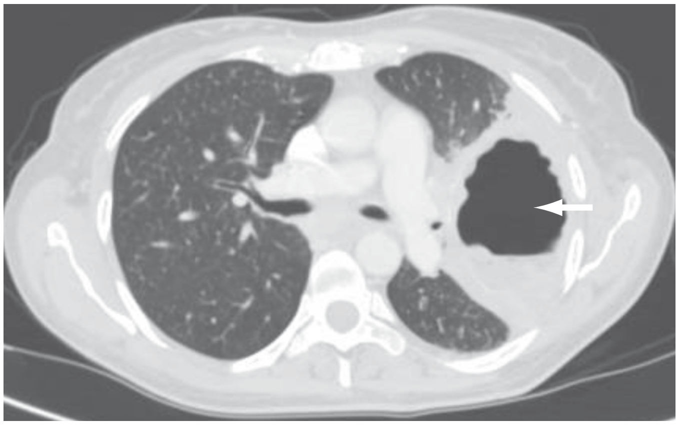

FIGURE 110.19 A chest computed tomography scan of a 43-year-old patient shows a left upper-lobe abscess *(arrow)*, a complication of pulmonary infection with *Streptococcus milleri.*

Other Bronchopulmonary Disorders

Broncholithiasis is characterized by a calcified node tightly adherent to a bronchus. It can cause sudden bleeding resulting from erosion into a small bronchial artery. Bright red blood occurs and usually stops with antitussive therapy or sedation. This type of hemoptysis is almost never massive (≥600 mL in 24 hours). Bronchoscopy during a bleeding episode can localize the site of the bleeding. Attempts to bronchoscopically remove the calcified node should not be undertaken. Nasal or pharyngeal lesions or hematemesis from a gastrointestinal source should be excluded.

Organizing pneumonia may replace lung parenchyma with scar tissue or persistent atelectasis or consolidation. If the shadow or mass persists over 6 to 8 weeks, resection is performed to exclude carcinoma. The differential diagnosis includes pneumonia, congenital abnormality, and aneurysm of the aorta.

Mycobacterial Infections

Mycobacterium tuberculosis is highly transmissible, infecting approximately 7% of exposed patients. Clinical tuberculosis develops in 5% to 10% of patients who are infected. In the primary phase of infection, exudative response progresses to caseous necrosis. Pulmonary tuberculosis tends to occur in apical and posterior segments of the upper lobes and superior segments of the lower lobes. Early in the postprimary phase, extensive caseation may coalesce into cavities that are frequently characterized by incomplete septations and lobulations. Erosion of septations supplied by bronchial arteries can cause hemoptysis and secondary infection. Healing occurs with fibrosis and contracture.

The mainstay of treatment is medical management with isoniazid, rifampin, ethambutol, streptomycin, and pyrazinamide. Bronchoscopy may be required for patients who do not respond to medical management. Cancer diagnosis should be considered for any newly identified mass, even with a positive tuberculosis skin test and acid-fast bacillus-positive sputum. In general, surgery for treatment of tuberculosis is reserved for patients with poor clinical response to medical therapy and who have pulmonary disease amenable to complete resection (lobectomy, wedge resection, or pneumonectomy).[41] Consideration of surgery for management of multidrug-resistant tuberculosis and extensively drug-resistant tuberculosis is warranted in the following circumstances: (1) persistently positive sputum cultures beyond 4 to 6 months of antituberculous therapy; (2) presence of extensive drug resistance that is unlikely to be cured with antituberculous therapy alone; or (3) presence of immediately life-threatening complications, such as massive hemoptysis or persistent bronchopleural fistula.

Surgical complications are doubled if the sputum is positive for *M. tuberculosis* and decreased if remaining lung tissue is fully expanded within the chest. Infectious complications include empyema, bronchopleural fistula, and endobronchial spread of the disease and are associated with a higher mortality rate. After surgery, a full course of antituberculous medical therapy should be prescribed for all patients.

Fungal Infections

Most fungal pulmonary infections are self-limited and do not require treatment. Intravenous or oral antifungal agents are the first-line therapy for severe or prolonged illness. Diagnosis is often made by sputum examination using potassium hydroxide preparations (Fig. 110.20) because fungal cultures require prolonged incubation before results are finalized. Papanicolaou test cytology and silver methenamine stain may also be used in diagnosis.

Histoplasma capsulatum is endemic to the Mississippi and Ohio River valleys and portions of the southwestern United States. Systemic infection causes histoplasmosis, the most common fungal infection in the United States. An inoculum (from the mycelial form found in soil, decaying materials, and bat or bird guano) produces an acute pneumonic illness in immunocompetent hosts, which is commonly subclinical and typically resolves without specific treatment. However, the lymphogenous reaction to *Histoplasma* can cause mediastinal lymph node enlargement, middle lobe syndrome, bronchiectasis, esophageal traction diverticulum, broncholithiasis with hemoptysis, tracheoesophageal fistula, constrictive pericarditis, or fibrosing mediastinitis with superior vena cava syndrome or other problems relating to compression of mediastinal structures. Additionally, lymphadenopathy may confound radiographic evaluation of the mediastinal lymph nodes in patients with lung cancer and may complicate diagnosis and treatment.

Coccidioidomycosis is endemic to the Southwest United States and is localized in the soil. Inhaling the organism results in a primary lung disease that is usually self-limited (see Fig. 110.20B). In endemic areas, coccidioidomycosis is a frequent cause of lung nodules, and resection may be required to rule out malignancy. Medical management is preferred. Surgery may be considered for treatment of cavitary disease or complications of cavitary disease.

Cryptococcosis is the second most common lethal fungal infection after histoplasmosis. Lungs are frequently involved, but the most common cause of death is related to central nervous system involvement with meningitis. Any patient diagnosed with pulmonary cryptococcosis should undergo lumbar puncture to rule out central nervous system involvement. Surgery may be required for open lung biopsy for diagnosis or to exclude lung cancer.

Aspergillosis is an opportunistic infection characterized by coarse fragmented septa and hyphae (see Fig. 110.20A). There are three aspergillosis clinical syndromes that typically affect immunocompromised hosts:

1. Aspergilloma: Fungus colonizes an existing lung cavity (commonly from tuberculosis). This is the most common presentation. CXR may demonstrate a crescent radiolucency next to a rounded mass. Invasion and destruction of parenchymal blood vessels occur within this cavity, placing patients at risk for hemorrhage. Prophylactic resection is controversial; although some physicians recommend resection if isolated disease is present in low-risk patients, surgery is typically reserved for massive/recurrent hemoptysis or to rule out neoplasm. The procedure of choice is lobectomy. The operation can be complex, with a significant inflammatory response within the hilum.

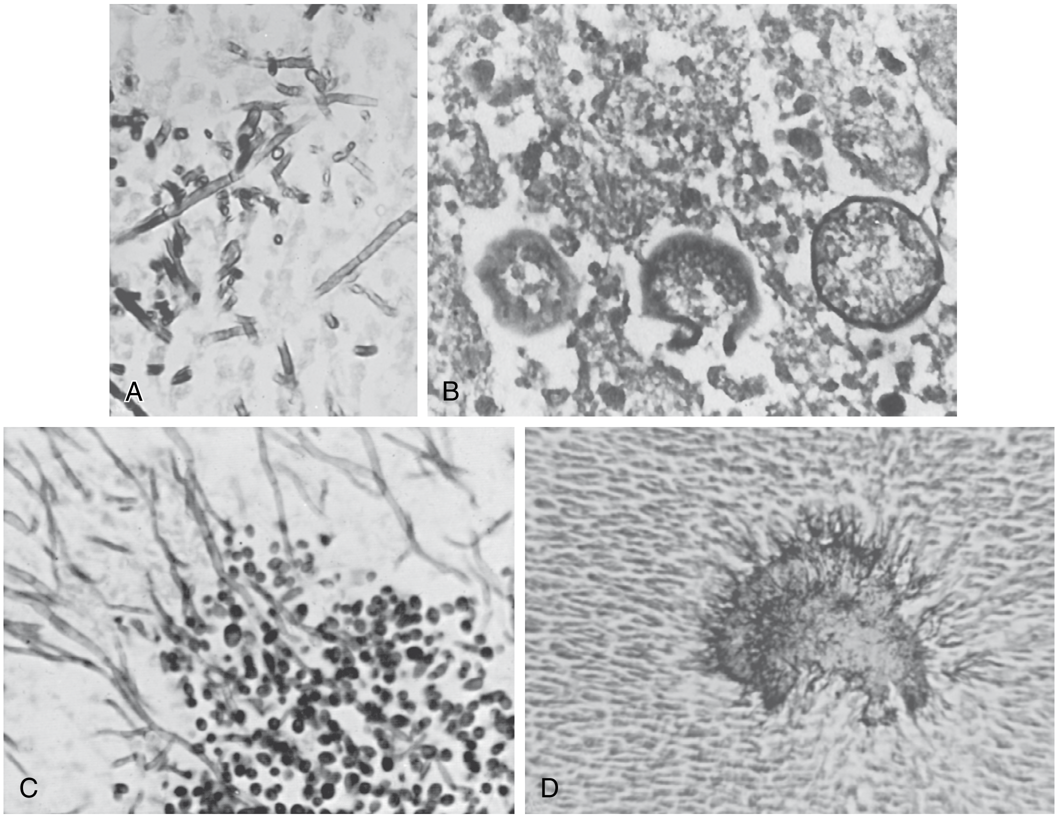

FIGURE 110.20 (A) The coarse, fragmented, septate mycelia of *Aspergillus fumigatus*. (B) Microscopic section of a coccidioidal granuloma (×400) shows spherules packed with endospores. (C) *Candida albicans* with both the mycelial and the yeast forms. (D) Actinomycotic granule shows branching filaments of a microscopic colony of *Actinomyces israelii*. (Gomori stain, ×250.) (A and C, From Takaro T. Thoracic mycotic infections. In: Walters W, ed. *Lewis' Practice of Surgery*. New York, NY: Hoeber Medical Division, Harper & Row; 1968. B, From Scott S, Takaro T. Thoracic mycotic and actinomycotic infections. In: Shields TW, ed. *General Thoracic Surgery*. 4th ed. Baltimore: Williams & Wilkins; 1994.)

2. Invasive pulmonary aspergillosis: This occurs in immunocompromised patients and manifests with chest pain, cough, and hemoptysis. The treatment is primarily medical, although lung biopsy may be necessary for diagnosis.
3. Allergic bronchopulmonary aspergillosis: This represents an allergic reaction to chronic *Aspergillus* colonization. It is diagnosed by bronchoscopy and usually treated medically. Rarely, resection is performed for localized bronchiectasis.

Mucormycosis is a rare, rapidly progressive fungal infection that occurs in immunocompromised patients, including patients with diabetes. The appearance is that of a black mold; it has wide nonseptate branching hyphae. The infection causes blood vessels to thrombose and lung tissue to infarct. Clinically, the rhinocerebral form occurs much more frequently than the pulmonary form of consolidation and cavities. Medical management involves cessation of steroids and antineoplastic drugs, initiation of amphotericin, and control of diabetes. The disease is often too advanced for effective treatment. Aggressive surgical and medical treatment may improve what is usually a grave prognosis.

Candida is a small, thin-walled budding yeast that is common in the environment but infects immunocompromised patients (see Fig. 110.20C). Lung involvement alone is rare. Surgery may be needed to confirm the diagnosis.

Pneumocystis carinii is an opportunistic fungal infection that is positive on silver methenamine stain. Bronchoalveolar lavage is diagnostic in more than 90% of patients. However, lung biopsy may be required to confirm the diagnosis.

Parasitic Infections

Surgery may also be used to manage the sequelae and complications of parasitic infections. *Entamoeba histolytica* infection is typically related to a liver abscess below the diaphragm via direct extension or lymphatic spread and is usually confined to the right lower thorax. Medical management with metronidazole is usually adequate, although tube drainage may be required in the case of empyema. Open resection is infrequently required.

Echinococcus infection may occur after hydatid cyst rupture, causing flooding of the lung or producing a severe hypersensitivity reaction. Nonoperative therapy for small asymptomatic calcified cysts may be considered. For larger symptomatic lesions, surgery includes simple enucleation via cleavage of planes between the cyst and the normal tissue. Aspiration and hypertonic saline 10% may be performed before enucleation. Positive pressure ventilation should be maintained until the cyst is out to prevent further contamination or hypersensitivity reaction.

Paragonimiasis is another common infection and cause of hemoptysis in Asia. In endemic areas, prevalence may be 5%, and hemoptysis from paragonimiasis must be differentiated from tuberculosis or lung cancer.

Actinomyces is a bacterium that is not found free in nature. It produces a chronic anaerobic endogenous infection deep within a wound. “Sulfur granules” draining from infected sinuses are microcolonies (see Fig. 110.20D). The cervicofacial form is the most common. The thoracic form usually occurs as pulmonary parenchymal disease resembling cancer. Penicillin is effective in medical management, but surgery may occasionally be required for radical excision of chest wall disease and empyema.

Nocardiosis is caused by an aerobic bacterium widely disseminated in soil and domestic animals; it was formerly rare, but incidence has been increasing in immunocompromised patients. It resembles actinomycosis by invading the chest wall and producing subcutaneous abscesses and sinuses that drain sulfur granules. Surgery is performed to exclude cancer, to obtain a diagnosis, or to treat complications of the disease. Medical therapy may include sulfonamides.

MASSIVE HEMOPTYSIS

Massive hemoptysis is a potentially fatal event that can lead to significant airway obstruction, abnormal gas exchange, or hemodynamic instability. In clinical practice, life-threatening hemoptysis occurs when there has been $>$150 mL of blood expectorated in a 24-hour period or hemorrhage at a rate of $\geq$100 mL/hour. The mortality rate with massive hemoptysis ranges from 7% to 30%, and deaths are related to asphyxiation rather than exsanguination. Bronchiectasis, tuberculosis, bronchogenic carcinoma, and fungal infections are the most common causes of massive hemoptysis.

The initial management principles for massive hemoptysis include establishing a patent airway, positioning the patient in lateral decubitus with the suspected bleeding lung in the dependent position, ensuring hemodynamic stability, correcting bleeding diathesis, and controlling hemorrhage. Intubation with a large-bore endotracheal tube is critical to secure the airway and allow for blood/thrombus extraction and bronchoscopy. However, if a patient has a stable airway and is able to cough up the blood on their own, intubation should be delayed. Flexible bronchoscopy is typically the preferred initial diagnostic examination, but rigid bronchoscopy can be helpful when superior visualization is needed because of large volumes of blood. If bronchoscopy fails to identify the source of hemoptysis, arteriography can be performed next because it can be diagnostic and therapeutic (via embolization). Once the patient is stabilized, a high-resolution CT scan of the chest should be performed to identify abnormalities that are difficult to detect by bronchoscopy, such as bronchiectasis.

Definitive therapy for massive hemoptysis is dependent on the underlying etiology. Local bronchoscopic options include iced saline lavage, topical agents (e.g., epinephrine or vasopressin), balloon tamponade, and ablative therapies. If these treatment measures fail at controlling hemorrhage, then angiographic catheterization with embolization may be used. Surgical lung resection may be indicated in cases of persistent or recurrent bleeding that are not amenable to bronchoscopic or angiographic intervention. Common complications of surgery for massive hemoptysis include empyema, bronchopleural fistula, postoperative pulmonary hemorrhage, lung infarction, respiratory insufficiency, wound infection, and hemothorax.

EMPHYSEMA AND DIFFUSE LUNG DISEASE

Emphysema

Emphysema is defined as dilation of the terminal air spaces that is accompanied by destruction of the air-space walls. Emphysema causes dyspnea through airflow limitation, hyperinflation, and impaired gas exchange resulting from a decrease in the alveolar and capillary surface area. Imaging findings include increased anteroposterior diameter, flattened diaphragm, and increased lung field lucency. The region of the acinus (includes respiratory bronchiole, alveolar ducts, alveolar sacs, and alveoli) that is affected by dilation or destruction determines the subtype of emphysema. Centrilobular emphysema affects the respiratory bronchiole, the central portion of the acinus, and is commonly associated with cigarette smoking and COPD. Panacinar emphysema affects all parts of the acinus and is a characteristic of α_1-antitrypsin deficiency. In paraseptal emphysema, the alveolar ducts are predominantly affected.

Medical management is the mainstay of treatment for emphysema and includes bronchodilators alone or in combination with antiinflammatory drugs such as corticosteroids and phosphodiesterase-4 inhibitors. Lung volume reduction surgery (LVRS), aimed at excising lung parenchyma with significant emphysematous involvement, may be beneficial in select patients who experience poor disease control despite maximal medical therapy. LVRS can improve elastic recoil, reduce dynamic hyperinflation, and decrease circulating inflammatory markers. A randomized trial comparing LVRS with medical therapy for severe emphysema found that LVRS yields a survival advantage for patients with both predominantly upper-lobe emphysema and low baseline exercise capacity.[42] Alternatively, lung volume reduction can be performed using endobronchial valves via bronchoscopy to reduce lung volume in selected patients without the need for surgery. In advanced cases of emphysema, lung transplantation may also be considered. Long-term survival after lung transplantation ranges from 65% at 3 years to 32% at 10 years.[43]

Diffuse Lung Disease

Common causes of diffuse lung disease (DLD) are infection, exposure to environmental agents, drug-induced pulmonary toxicity, sarcoidosis, and radiation-induced lung injury (Box 110.1). CXR findings of an alveolar pattern (fluffy with air bronchograms) or an interstitial pattern (ground-glass or granular appearance) can be suggestive of DLD. Patients may be mildly symptomatic or progress to a critically ill state requiring intensive care and ventilation support. A lung biopsy may be indicated to confirm or exclude a specific diagnosis before medical therapy is initiated (e.g., cyclophosphamide for granulomatosis with polyangiitis (GPA)).

Sarcoidosis is a potential etiology for DLD and commonly presents with dyspnea and a dry cough. Sarcoidosis is associated with immune-mediated, widespread noncaseating granulomas and bilateral hilar mediastinal lymphadenopathy. Severe progressive pulmonary fibrosis may develop in 10% to 20% of patients. Bronchoscopic pulmonary biopsy is the initial diagnostic procedure. In select cases, biopsy of mediastinal lymph nodes may also be performed. Steroids are the mainstay of treatment.

Lung biopsy may be required in cases of progressive interstitial parenchymal changes after failed attempts at developing a diagnosis with less invasive approaches (e.g., transthoracic needle aspiration or transbronchial lung biopsy). Although biopsy specimens can be obtained by VATS, thoracotomy may be required in select cases because of severe pleural disease, high bleeding risk, or more severe respiratory impairment. The optimal number, size, and location of lung biopsies depend on the suspected diagnosis and the anatomic distribution of the DLD. High-resolution CT imaging is essential to guide the optimal locations for biopsy. Typically, biopsy specimens are obtained from multiple lobes of the lung and from areas of varying disease severity because this aids with diagnostic accuracy (Box 110.2).

BOX 110.1 Classification of Diffuse Lung Diseases

- Infections (more commonly cause focal disease, granuloma formation)
  - Viruses—especially influenza, cytomegalovirus
  - Bacteria—tuberculosis, all types of regular bacteria, Rocky Mountain spotted fever
  - Fungi—all types can cause diffuse disease
  - Parasites—Pneumocystis species infection, toxoplasmosis, paragonimiasis, among others
- Occupational causes
  - Mineral dusts
  - Chemical fumes—NO_2 (silo filler disease), Cl, NH_3, SO_2, CCl_4, Br, HF, HCl, HNO_3, kerosene, acetylene
- Neoplastic disease
  - Lymphangitic spread
  - Hematogenous metastases
  - Leukemia, lymphoma, bronchioloalveolar cell cancer
- Congenital—familial
  - Niemann-Pick disease, Gaucher disease, neurofibromatosis, tuberous fibrosis
- Metabolic and unknown
  - Liver disease, uremia, inflammatory bowel disease
- Physical agents
  - Radiation, O_2 toxicity, thermal injury, blast injury
- Heart failure and multiple pulmonary emboli
- Immunologic causes
- Hypersensitivity pneumonia
  - Inhaled antigens
  - Farmer lung (actinomycosis)
  - Bagassosis (sugar cane)
  - Malt workers (*Aspergillus* spp.)
  - Byssinosis (cotton)
- Drug reactions
  - Hydralazine, busulfan, nitrofurantoin (Macrodantin), hexamethonium, methysergide, bleomycin
- Collagen diseases
  - Scleroderma, rheumatoid disease, systemic lupus erythematosus, dermatomyositis, Wegener granulomatosis, Goodpasture syndrome
- Other
  - Sarcoidosis
  - Histiocytosis
  - Idiopathic hemosiderosis
  - Pulmonary alveolar proteinosis
  - Diffuse interstitial fibrosis, idiopathic pulmonary fibrosis
  - Desquamative interstitial pneumonia
  - Eosinophilic pneumonia (Note: Some are caused by drugs, actinomycosis, and parasites.)
  - Lymphangioleiomyomatosis

Adult Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) is caused by an alveolar insult that results in the release of proinflammatory cytokines, capillary endothelial damage, increased vessel permeability, leakage of protein-rich fluid into alveoli, and noncardiogenic pulmonary edema. Sepsis, aspiration, pneumonia, trauma, and pancreatitis are common causes of ARDS. Imaging demonstrates bilateral lung opacities secondary to increased interstitial fluid in a patient with respiratory insufficiency (Fig. 110.21). ARDS is associated with a high rate of morbidity as a result of impaired gas exchange, decreased lung compliance, and pulmonary hypertension. Prompt recognition and treatment of ARDS is critical to reduce the risk of mortality.

The severity of ARDS is defined according to the degree of hypoxemia, as follows: mild ($200 \text{ mm Hg} > PaO_2/FiO_2 \leq 300 \text{ mm Hg}$), moderate ($100 \text{ mm Hg} > PaO_2/FiO_2 \leq 200 \text{ mm Hg}$), and severe ($PaO_2/FiO_2 \leq 100 \text{ mm Hg}$). The risk of mortality increases with more severe ARDS. Treatment is medical and directed toward improving oxygenation and addressing the underlying cause. The key principles in ventilation management for ARDS include using

BOX 110.2 Miscellaneous Lung Tumors

- Hamartoma
- Epithelial origin tumors
  - Papilloma—single or multiple, squamous epithelium, occurs in childhood, probably viral, may require bronchial resection but frequently recur
  - Polyp—inflammatory-squamous metaplasia on a stalk; bronchial resection may be needed; these do not usually recur
- Mesodermal origin tumors
  - Fibroma—most frequent mesodermal tumor
  - Chondroma
  - Lipoma
  - Leiomyoma—intrabronchial or peripheral; conservative resection
- Granular cell tumors
  - Rhabdomyoma
  - Neuroma
  - Hemangioma—subglottic larynx or upper trachea of infants; radiation therapy
  - Lymphangioma—similar to cystic hygroma; upper airway obstruction in neonates
  - Hemangioendothelioma—newborn lungs, often progressive and lethal
  - Lymphangiomyomatosis—rare, slowly progressive; death from pulmonary insufficiency; fine, multinodular lesions, loss of parenchyma and honeycombing; usually females in their reproductive years
  - Arteriovenous fistula—congenital, right-to-left shunt; cyanosis, dyspnea on exertion, clubbing, brain abscess; associated with hereditary hemorrhagic telangiectasia of lower lobes
- Inflammatory tumors and pseudotumors
  - Plasma cell granuloma
  - Pseudolymphoma
  - Xanthoma
- Teratoma

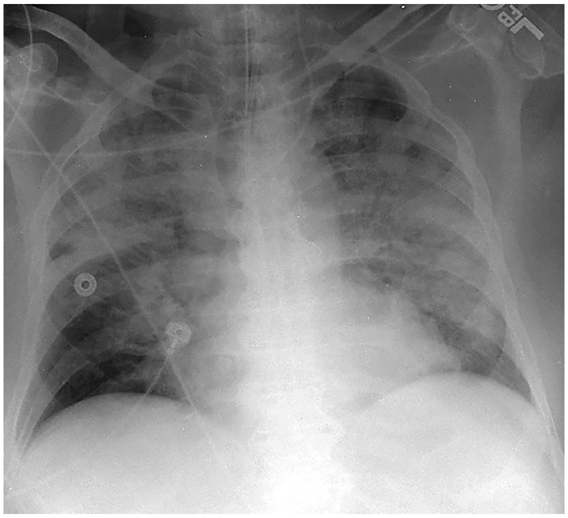

FIGURE 110.21 Chest radiograph of acute respiratory distress syndrome. Frontal chest radiography in a mechanically ventilated patient shows extensive, multifocal, bilateral lung opacities, essentially involving all lobes and without features suggesting increased pressure edema, such as interlobular septal thickening or pleural effusion. (From Lee, WL, Herridge MS, Binnie A. Acute respiratory distress syndrome In: Lazarus SC, Sarmiento KF, Schnapp LM, et al. *Murray and Nadel's Textbook of Respiratory Medicine*. 7th ed. Elsevier; 2022.)

applied positive end-expiratory pressure (PEEP) to maximize alveolar recruitment and low tidal volumes to prevent alveolar overdistention. In select patients who do not improve with these supportive measures, prone positioning, neuromuscular blockers, or mechanical support with ECMO may be considered in a stepwise fashion.

PULMONARY METASTASES

Lung metastases represent a manifestation of systemic spread of a primary extrapulmonary neoplasm. Pulmonary metastasectomy in appropriately selected patients may offer an opportunity for prolonged disease-free survival. The 5- and 10-year survival rates after complete pulmonary metastasectomy are 36% and 26%, respectively.[44] General criteria used for consideration of pulmonary metastasectomy include ability to completely resect all areas of pulmonary involvement, controllability of the primary tumor, absent extrapulmonary metastatic disease, and adequate cardiopulmonary reserve. If these criteria are unable to be met, radiation therapy may be used to treat the local manifestations of metastatic disease, particularly in the presence of bony or symptomatic metastases. The decision to proceed with pulmonary metastasectomy should involve a multidisciplinary approach with evaluation by medical oncology, radiation oncology, and thoracic surgery.

Certain prognostic indicators may be used to select patients with more favorable disease-free and overall survival expectations. Pulmonary metastasectomy is considered best suited for patients with three or fewer metastases. Complete resection of all pulmonary metastases has been consistently associated with improved survival in comparison to incomplete resection. There also does appear to be a better prognosis for patients with germ cell tumors, disease-free intervals of 36 months or more, and single metastases.[44]

Open thoracotomy was traditionally the recommended approach for pulmonary metastasectomy because it allows for bimanual palpation of the lungs to identify potential occult metastases. However, VATS is considered a safe alternative, given the significant advancement in imaging techniques that can detect small pulmonary lesions with greater accuracy before surgery. Intraoperatively, obtaining tumor-free and adequate margins is critical for reducing future risk of recurrence. After resection, close follow-up with imaging at regular intervals should be performed to monitor for disease recurrence.

MISCELLANEOUS LUNG TUMORS

Hamartomas are the most common benign lung tumor and consist of an abnormal distribution of normal lung tissue elements, such as cartilage and connective tissue. They typically present after the fifth decade of life and are more frequently found in males. These lesions are slow-growing and often peripherally located. On imaging, these masses present as coin-shaped and solitary, with sharply demarcated edges, typically measuring <4 cm in diameter. Calcifications can be present and give the lesion its pathognomonic "popcorn" appearance. A cystic adenomatoid malformation represents a developmental hamartomatous abnormality of the lung, which occurs in infants as cysts or immature, malformed lung tissue.

SCC, adenocarcinoma, large cell carcinoma, and small cell carcinoma account for most primary malignant lung cancers. However, slow-growing lung tumors may arise from the epithelium, ducts, and glands of the bronchial tree and account for 1% to 2% of all lung neoplasms. Most of these tumors are of low-grade malignant potential.

Primary pulmonary ACC is a rare, slow-growing malignancy that typically involves the trachea and mainstem bronchi. It arises from the tracheobronchial glands in the airway submucosa and is histologically similar to ACC arising in the salivary glands. ACC may present with nonspecific symptoms, such as cough or dyspnea, given their location in the trachea and mainstem bronchi and potential for distal obstruction. These tumors can metastasize and involve perineural lymphatics or distant organs. Surgical resection is the mainstay of treatment. However, radiation therapy has been used in select cases.

Sarcomatoid carcinomas represent a rare subtype of NSCLC. These tumors have a malignant epithelial component mixed with features typically found in sarcomas. Sarcomatoid carcinoma is associated with worse survival compared with nonsarcomatoid lung cancers. Pleomorphic carcinomas are the most common subtype of sarcomatoid carcinoma, and variants include spindle cell and giant cell carcinomas.

Pulmonary lymphoma most commonly occurs as disseminated lymphoma involving the lung. Disseminated lymphoma occurs in 40% of patients with Hodgkin disease and 7% of patients with non-Hodgkin disease. Primary pulmonary lymphomas are rare. The diagnosis is usually made at the time of surgery. A thorough evaluation focused on ruling out other potential sites of primary lymphoma should be performed if the diagnosis of primary pulmonary lymphoma is suspected preoperatively.

NEUROENDOCRINE TUMORS OF THE LUNG

Several types of neuroendocrine lung tumors exist, including small cell carcinoma, large cell neuroendocrine carcinomas, typical (low-grade) carcinoid, and atypical (intermediate-grade) carcinoid. Of the NETs, small cell and large cell neuroendocrine carcinomas are characterized by having a more aggressive clinical course and a much higher mitotic rate on pathologic analysis. Meanwhile, typical and atypical pulmonary carcinoids have similar features to carcinoid tumors arising at other sites and have relatively indolent clinical behavior. NETs are usually positive for chromogranin or synaptophysin expression.

Carcinoid tumors, arising from bronchial Kulchitsky or enterochromaffin cells (amine precursor uptake and decarboxylation cells), account for approximately 1% to 2% of all lung malignancies in adults and approximately 20% to 30% of all NETs. Carcinoid tumor is the most common primary lung neoplasm in children. These tumors may present with a cough or wheeze, hemoptysis, chest pain, or recurrent pneumonia resulting from bronchial obstruction. On imaging, most tumors appear as round or ovoid lesions that range in size from 2 to 5 cm. Carcinoid syndrome may infrequently occur as a result of systemic release of vasoactive substances, such as serotonin, and cause acute symptoms, including flushing, tachycardia, wheezing, and diarrhea.

Surgical resection is the preferred treatment approach for patients with localized lung NETs and adequate pulmonary reserve. Transbronchoscopic resection may be an alternative treatment approach for select typical (low-grade) carcinoid tumors. Lymph node metastasis is relatively common and occurs in 5% to 20% of typical carcinoid tumors and 30% to 70% of atypical tumors. As such, mediastinal lymph node sampling or dissection at the time of surgery is recommended, along with complete resection of nodal metastasis, if feasible. Typical carcinoid tumors exhibit a relatively good prognosis (~90%, 5-year survival), whereas atypical carcinoid tumors demonstrate a 5-year survival of about 50%.[45] The highly malignant large cell and small cell neuroendocrine carcinomas have 5-year survivals of 15% to 57% and <5%, respectively.[45]

CHEST WALL

Congenital Deformities

There are a variety of thoracic congenital abnormalities that manifest as defects of the anterior chest wall, including pectus excavatum, pectus carinatum, pouter pigeon breast, Poland syndrome, and cleft sternum (Fig. 110.22). The clinical significance

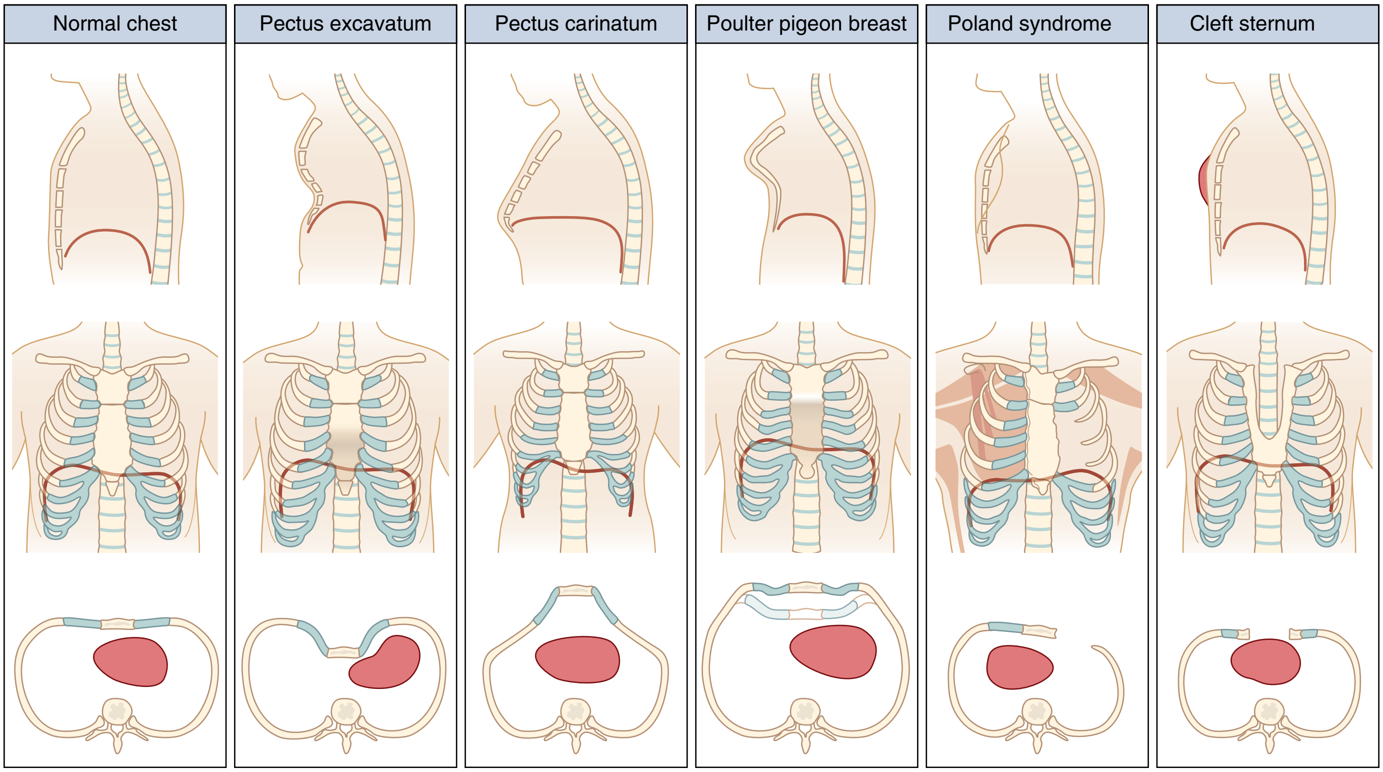

FIGURE 110.22 Classification of chest wall deformities. (From Fokin AA, Steuerwald NM, Ahrens WA, et al. Anatomical, histologic, and genetic characteristics of congenital chest wall deformities. *Semin Thorac Cardiovasc Surg.* 2009;21:44-57.)

of these deformities depends on the severity of the chest wall defect, cardiopulmonary morbidity, and the psychosocial implications of the defect on the patient.

Pectus Excavatum

Pectus excavatum, or "funnel chest," is the most common congenital chest wall deformity, occurring in approximately 1 of 400 live births, and is characterized by a concave sternal depression. This deformity has a male predominance (4:1) and is usually sporadic but may be associated with other connective tissue disorders (e.g., Marfan syndrome) and genetic conditions (e.g., Noonan syndrome). The exact cause of pectus excavatum is unclear, but it is presumed to be a result of disproportionate muscular force on the sternum and costal cartilages or abnormal growth of cartilage or rib. Although cosmesis is the most frequently reported concern, exercise tolerance, chest discomfort, and shortness of breath can also occur.

Initial evaluation should focus on identifying the severity of the deformity and the presence of any associated anomalies. Pectus excavatum may be symmetric or asymmetric, with the sternum rotated toward one side. CT with 3D reconstruction can aid in determining the impact of the pectus defect on the lungs, heart, and major blood vessels and provide measurements of the thoracic cavity. The Haller index, a ratio of the transverse diameter of the chest to the anterior-posterior diameter at its most narrow point, can be derived from a CT scan and is a standardized method for determining candidacy for surgical repair (Fig. 110.23). Patients with significant displacement of the heart or respiratory symptoms should have a cardiology evaluation with echocardiography and pulmonary function testing, respectively.

Surgery is usually performed during late childhood or early adolescence and is generally considered for patients with a Haller index of >3.25, cardiac abnormalities, restrictive respiratory disease, or significant patient concern about appearance. Two surgical approaches are actively used: the Nuss and modified Ravitch procedures. The Nuss procedure corrects the defect by using a custom-contoured, convex steel bar to apply outward pressure to the sternum. This procedure can be performed minimally invasively and entails placing a steel "Nuss" bar in the pleural space, passing it behind the sternum under thoracoscopic guidance, rotating it 180 degrees, and then attaching it laterally to the rib cage. The bar is typically removed after about 2 years. Other methods of surgical correction include the basic steps described by Dr. Ravitch in 1949. These include bilateral parasternal and subperichondrial resection of the deformed costal cartilages, detachment of the xiphoid process, transverse anterior table wedge osteotomy at the upper edge of the sternal depression, bending the sternum anteriorly to straighten its course, and securing the corrected position of the sternum (Fig. 110.24). The sternal support is typically kept in place for about 1 year. Permanent plates are also being used to avoid a second operation and reduce the rate of recurrence.

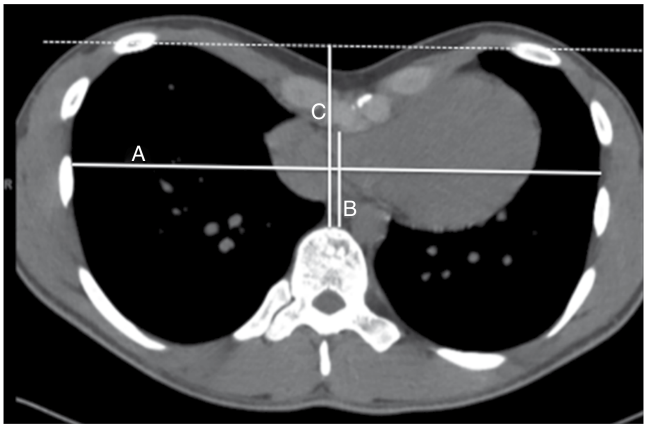

FIGURE 110.23 Illustration of pectus indices calculated from the computed tomography axial image. Haller index (HI) is measured by dividing the maximum transverse diameter of the chest wall *(line A)* by the minimum anterior-posterior distance *(line B)*. The correction index (CI) is calculated by measuring the distance between the posterior aspect of the corrected sternum and the anterior aspect of the vertebra *(line C)*. (From Poston PM, Patel SS, Rajput M, et al. The correction index: setting the standard for recommending operative repair of pectus excavatum. *Ann Thorac Surg.* 2014;97[4]:1176-1179; discussion 1179-1180.)

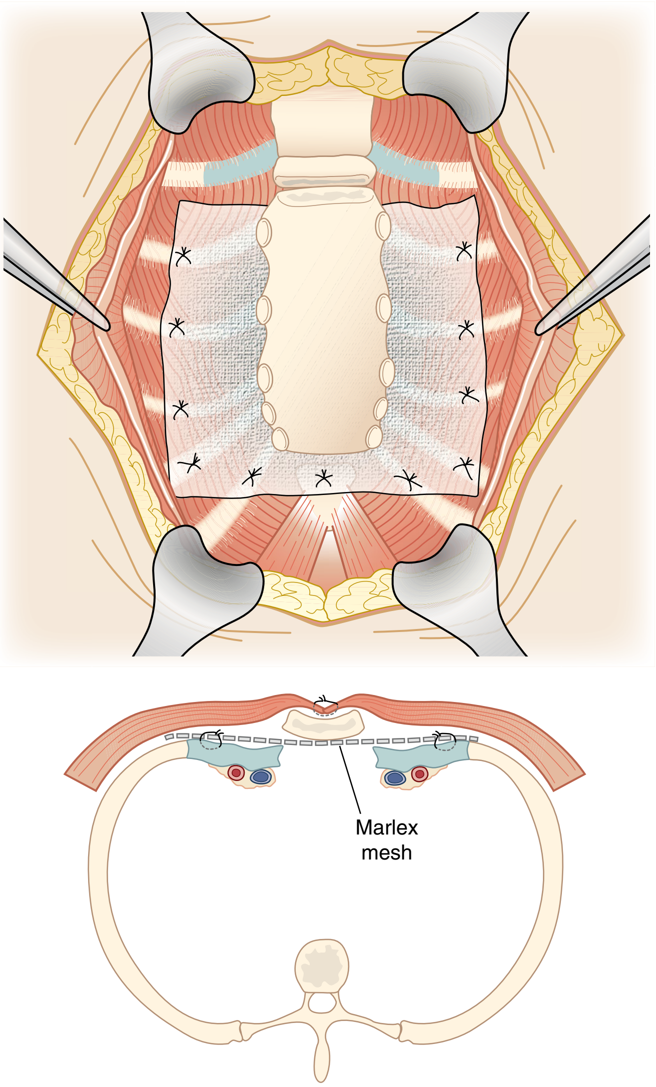

FIGURE 110.24 Surgical repair of pectus excavatum: Robicsek method. Subperichondrial bilateral resection of the deformed costal cartilages. Transverse wedge sternotomy. Detachment of xiphoid process and perichondrial and intercostal strips of the sternum. Sternum bent forward. Sternal support is achieved with Marlex mesh sutured taut to the resected costal cartilages. Xiphoid process reattached to the mesh. *Insert:* Cross-sectional view. Intact internal thoracic vessels. Sternum in corrected position rests on the mesh hammock. (From Robicsek F, Watts LT, Fokin AA. Surgical repair of pectus excavatum and carinatum. *Semin Thorac Cardiovasc Surg.* 2009;21:64-75.)

Pectus Carinatum

Pectus carinatum, also called *pigeon chest,* is defined by outward protrusion of the sternum and costal cartilages. It occurs in 1/1500 live births. As with pectus excavatum, the exact cause is unknown, and there is a male predominance. It typically presents in early adolescence and is often undiscovered until the pubertal growth spurt. For most patients, cosmesis is the primary concern, but some may experience exertional dyspnea, respiratory infections, or asthma. Associated musculoskeletal and spinal anomalies, especially scoliosis, are common.

There are two primary types of pectus carinatum deformity: chondrogladiolar prominence (or keel chest) and chondromanubrial prominence (or pouter pigeon breast). Of these, chondrogladiolar prominence is more common and is characterized by forward protrusion of the middle and lower portions of the sternum. The costal cartilages are concave and usually symmetrically depressed, accentuating the sternal prominence (Fig. 110.25). In contrast, chondromanubrial prominence is characterized by anterior protrusion of the upper portion of the sternum and posterior deviation of the body of the sternum, resulting in a short and angled sternum. This pectus deformity is presumed to be a result of premature ossification of the sternum.

Bracing is an effective treatment for patients with flexible chest walls and mild to moderate pectus carinatum. Corrective bracing has been shown to have an 85% success rate.[46] Surgery is typically reserved for those with complex deformities, inflexible chest walls (e.g., patients in postpuberty), or severe sternal asymmetry. Surgical repair should be performed at the end of the pubertal growth spurt. Repair is typically performed using a modified Ravitch procedure that involves resection of abnormal costal cartilages while preserving the perichondrium (from which new cartilage grows), sternal osteotomy, and reshaping/repositioning of the sternum (Fig. 110.26).

Poland Syndrome and Cleft Sternum

Poland syndrome is a rare congenital anomaly that is characterized by absence of the pectoral muscles, most commonly unilateral. Associated anomalies may include absence or deformity of other chest wall muscles, breast tissue, nipple, costal cartilages of ribs 2 to 5, and digits (e.g., syndactyly). The pathogenesis of Poland syndrome remains unclear, with the prevailing theory being disruption of the subclavian artery blood supply. Although most patients do not develop respiratory symptoms, those with missing ribs may have paradoxical respiratory motion of the chest wall (inward movement during inspiration), similar to a flail chest.

Cleft sternum is a rare congenital defect resulting from failed midline fusion of the sternum. This can result in paradoxical respiratory movements and leaves the heart and mediastinal structures unprotected from direct injury. Surgical correction is recommended in the neonatal period.

Chest Wall Tumors

Chest wall tumors represent a heterogeneous group of rare benign and malignant tumors (Table 110.4). Tumors can be primary to the chest wall, arise from direct extension from a primary lung cancer, or result from metastasis from another site. More than 50% of chest wall tumors are malignant, with the majority of these malignant tumors arising from the bone, cartilage, or soft tissue. Overall 5-year survival after resection of primary chest wall neoplasms is 57%.[47] These tumors often present with a palpable painful mass or as an incidental finding on chest radiography. CT can demonstrate the extent of bone, soft tissue, and pleural and mediastinal involvement and identify any pulmonary metastases. MRI can further delineate soft tissue, vascular, and nerve involvement and the presence of spinal cord or epidural extension. Tissue biopsy can confirm the diagnosis and inform the selection of potential therapy strategies.

TABLE 110.4 Classification of Tumors of the Chest Wall

	BENIGN (40%)	MALIGNANT (60%)
Bone Tumors		
Bone	Osteoblastoma	Ewing sarcoma
	Osteoid osteoma	Osteosarcoma
Cartilage	Chondroma (enchondroma)	Chondrosarcoma
	Osteochondroma	
Fibrous tissue	Fibrous dysplasia	
Bone marrow	Eosinophilic granuloma	Solitary plasmacytoma
Osteoclast	Aneurysmal bone cyst	
	Giant cell tumor (osteoclastoma)	
Vascular	Hemangioma	Hemangiosarcoma
	Cystic angiomatosis	
Other	Mesenchymal hamartoma	
Soft Tissue Tumors		
Adipose tissue	Lipoma	Liposarcoma
	Ossifying lipoma	
Fibrous tissue	Fibroma (desmoid tumor)	Fibrosarcoma
	Ossifying fibroma	MFH
Muscle	Leiomyoma	Leiomyosarcoma
	Rhabdomyoma	Rhabdomyosarcoma
		Tendon sheath sarcoma
Nerve	Neurofibroma	Askin tumor (PNET)
	Schwannoma (neurilemoma or neurinoma)	Malignant schwannoma
		Neurofibrosarcoma
		Neuroblastoma
Vascular	Hemangioma	Hemangiosarcoma
	Vascular leiomyoma	
Other		Hodgkin disease
		Leukemia
		Lymphoma
		Lymphosarcoma
		Mixed sarcoma
		Reticulosarcoma

MFH, Malignant fibrous histiocytoma; *PNET*, primitive neuroectodermal tumor.

From Smith SE, Keshavjee S. Primary chest wall tumors. *Thorac Surg Clin.* 2010;20:495-507.

The indication for surgery is based on evaluation of the tumor histology, location, degree of local invasion, and presence of metastases. Complete R0 tumor resection and reconstruction of the chest wall defect is the main principle of surgical management for chest wall tumors, except for Ewing sarcoma (treated with systemic chemotherapy and definitive local therapy) and solitary plasmacytomas (treated with radiation). Therefore, most tumors over a few centimeters should have a core-needle biopsy to help guide therapy. Resections that include three or more ribs will generally require reconstruction with prosthetic material to preserve chest wall mechanics. Synthetic materials that can be used include polypropylene, polytetrafluorethylene patch, methyl methacrylate, and osteosynthesis system with titanium implantable material (Fig. 110.27). These reconstructive techniques are mainly used to improve chest wall stability to prevent flail segments and postoperative respiratory compromise. Malignant tumors of the manubrium, sternum, clavicle, and scapula generally require excision of the entire bone and surrounding soft tissue to ensure negative margins. Chest wall closure of a small defect for a small lesion can usually be done primarily. Large tumors in which a considerable defect is anticipated, both skeletal reconstruction and soft tissue coverage are often necessary. Local thoracic pedicle or myocutaneous flaps are generally used for reconstruction of large defects and include pectoralis major, latissimus dorsi, and serratus anterior muscles. As such, chest wall resections requiring complex reconstructions should be approached in a multidisciplinary fashion, with preoperative consultation with both a thoracic and plastic surgeon.

Bone Tumors

Benign chest wall tumors include enchondromas (benign bone tumor), osteochondromas (benign cartilage tumor), fibrous dysplasia, eosinophilic granuloma (Langerhans cell histiocytosis), lymphangiomas, and desmoid tumors. The main goal of surgical

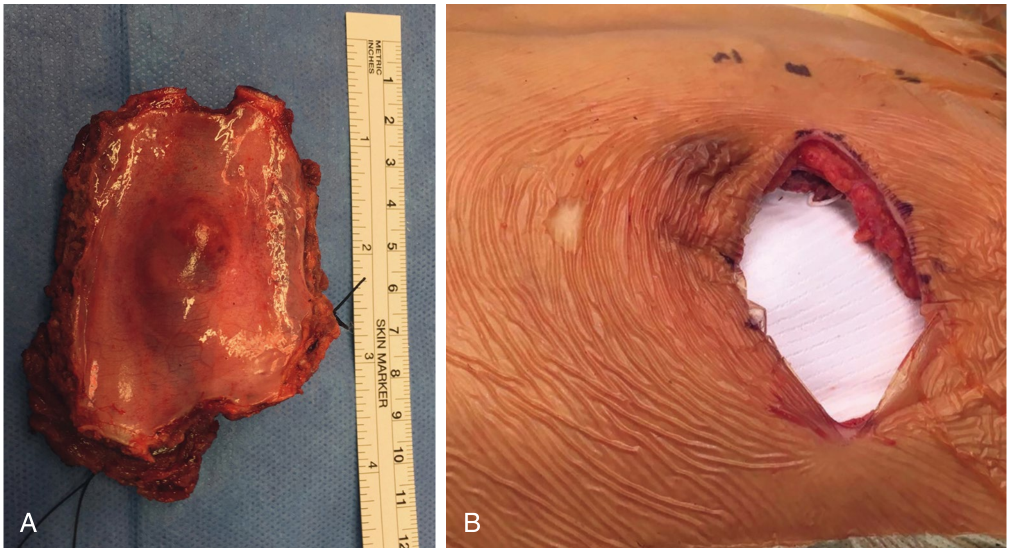

FIGURE 110.27 Chest wall synovial sarcoma in a 9-year-old child. (A) Shown is a segment of the left chest wall (ribs 3 and 4). Complete resection was performed. The macroscopic clear margins are verified in final pathology. (B) Reconstruction of chest wall defect with a synthetic polytetrafluoroethylene Gore-Tex patch.

resection is to provide symptomatic relief and minimize the risk of future malignant transformation. Chondromas account for about 20% of benign chest wall tumors. In comparison to benign lesions, malignant chest wall tumors are frequently more rapidly growing and often present at a larger size. Chondrosarcoma is the most common malignancy of the chest wall, making up approximately 30% of primary malignancies, and typically presents as a painful, hard, fixed mass. Resection with wide margins of 2 to 4 cm is the treatment of choice because these tumors are generally resistant to radiation and chemotherapy. However, given the location and size of the tumor, wide margins may be difficult to obtain. Primary osteosarcomas of the chest wall account for 10% to 15% of malignant tumors and commonly involve the rib, scapula, and clavicles. The tumor grows rapidly, and radiographic characteristics include a sunburst pattern on CXR. Ewing sarcoma accounts for 5% to 10% of chest wall malignancies. The radiographic characteristics include an onion-peel appearance with periosteal elevation and bony remodeling. With multimodality therapy, 5-year survival is about 50%. Primary solitary plasmacytoma is a rare chest wall tumor that commonly occurs in older males as a painful solitary tumor arising from plasma cells and can progress to multiple myeloma. Radiographic characteristics include a diffuse, moth-eaten, or punched-out appearance of the bone. Systemic disease can be confirmed using serum protein electrophoresis, urinalysis (Bence-Jones protein), and bone marrow aspiration. Radiotherapy is recommended for solitary plasmacytoma.

Soft Tissue Tumors

Soft tissue sarcomas are the most common primary malignant soft tissue chest wall lesions. Malignant fibrous histiocytomas and rhabdomyosarcoma are the most common subtypes. Long-term survival after resection is acceptable, with a reported 5-year survival of 73%.[48] Recurrence occurs in about 20% of patients. Negative margins are an important predictor of local recurrence; therefore, the chest wall may need to be resected to achieve clear margins.

Metastatic Tumors

Metastatic neoplasms may involve the chest wall through direct extension or lymphatic or hematogenous spread. For example, lung and breast cancer can metastasize to or recur in the chest wall. Surgery may be indicated for local disease control on a case-by-case basis.

Chest Wall Infections

Chest wall infections share similar risk factors for infection at other surgical sites, such as poor nutritional status, immunocompromised state, diabetes, smoking, and obesity. Adequate therapy involves antibiotics and source control. Necrotizing soft tissue infections (NSTIs) that involve the thorax typically spread from elsewhere, most commonly the extremities, and require urgent surgical debridement. Most of the reported NSTIs of the chest wall develop as a result of the treatment of other pathologies, such as chest tube placement for empyema. The classical symptoms of NSTIs are erythema, pain out of proportion to exam, crepitus and induration, and skin bullae. Systemic toxicity can present with hypotension, fever, and severe sepsis.

Patients with a history of intravenous drug use are at increased risk for developing septic arthritis of the sternoclavicular, sternochondral, and manubriosternal joints. CXR, CT, or MRI can be used to evaluate the joint. Positive findings include widening of the joint space; joint destruction; and osteomyelitis of the clavicle, manubrium, or first rib. Sternoclavicular joint infections are typically seen with systemic infection and can be treated with surgical debridement, en bloc resection, and antibiotic therapy. Furthermore, postoperative sternal wound infections can occur after median sternotomy or cardiac surgery. Spontaneous primary chest wall infections can also arise from a variety of sources as a consequence of immunosuppression, drug-resistant organisms, tuberculosis, or HIV infection.

Chest Wall Trauma

Blunt thoracic trauma comprises 20% to 25% of all traumas, with the most common etiology being motor vehicle collisions (MVCs).

Blunt chest trauma can result in injuries to multiple vital thoracic structures, including the clavicle, ribs, and sternum. A definitive diagnosis of traumatic chest wall injuries can be made with CXR or CT scan.

Rib fractures occur in almost two-thirds of patients with significant chest trauma after MVCs. Ribs 4 to 10 are more susceptible to traumatic injury than the superior ribs, which are protected by the clavicle, scapula, and overlying soft tissue. Physical exam may reveal focal tenderness, bony crepitus, or ecchymosis overlying a fractured rib. Diminished or absent breath sounds may represent splinting from the pain but may also reflect the presence of a pneumothorax or hemothorax. The mainstay of rib fracture management is pain control. Early and adequate analgesia and lung volume expansion treatments (e.g., incentive spirometry, deep breathing, coughing) help prevent pulmonary complications, such as pneumonia, resulting from splinting and atelectasis. Advanced age, smoking, and underlying lung disease are poor prognostic factors. Underlying injury to the liver, spleen, and kidney should be ruled out in the case of fractures to the lower ribs (ninth and lower). Patients with three or more rib fractures should be admitted for hospitalization, given the increased risk of morbidity and mortality. The majority of rib fractures do not require stabilization or plating, but this continues to be an active area of investigation.

Flail chest is defined as fractures of three or more ribs in two or more places, which results in a paradoxical motion of the chest wall during respiration (e.g., inward during inspiration and outward during expiration). It has been associated with a mortality rate of 16%.[49] Flail chest is often associated with an underlying pulmonary contusion and should be supported with pain relief, rib stabilization, or even mechanical ventilation. Early operative treatment reduces pulmonary complications, the duration of mechanical ventilation, hospital length of stay, and mortality for patients with flail chest.

Sternal injuries may result from blunt trauma to the anterior chest wall, typically from a driver striking the steering column during an MVC. Isolated sternal fractures tend to heal without any need for surgical intervention. However, sternal fractures are associated with an increased risk of internal injury and mortality in polytrauma patients. An underlying cardiac injury, such as aortic disruption, cardiac contusion, pericardial effusion, or arrhythmia, should be considered. An electrocardiogram should be obtained in patients with sternal fracture to assess for myocardial injury. Nondisplaced sternal fractures can usually be managed with good pain control. Fractures of the proximal third of the clavicle can be associated with sternal fracture or intrathoracic injury. Nonoperative management with ice, analgesics, and a sling for support is the initial treatment strategy for nondisplaced proximal clavicle fractures.

THORACIC OUTLET SYNDROME

Thoracic outlet syndrome (TOS) refers to compression of the subclavian vessels and nerves of the brachial plexus (Fig. 110.28) in the region of the thoracic inlet. The three types of TOS are neurogenic (most common), arterial, and venous (Table 110.5). Middle-aged females are most commonly affected by TOS. The thoracic outlet contains three notable structures: the brachial plexus, subclavian artery, and subclavian vein. These structures can be compressed at various locations as they pass between the thoracic inlet and the upper extremity (see Fig. 110.33). From medial to lateral, these anatomic regions are as follows: interscalene triangle (artery and nerves), costoclavicular space (vein), and subcoracoid area (artery, vein, nerves).

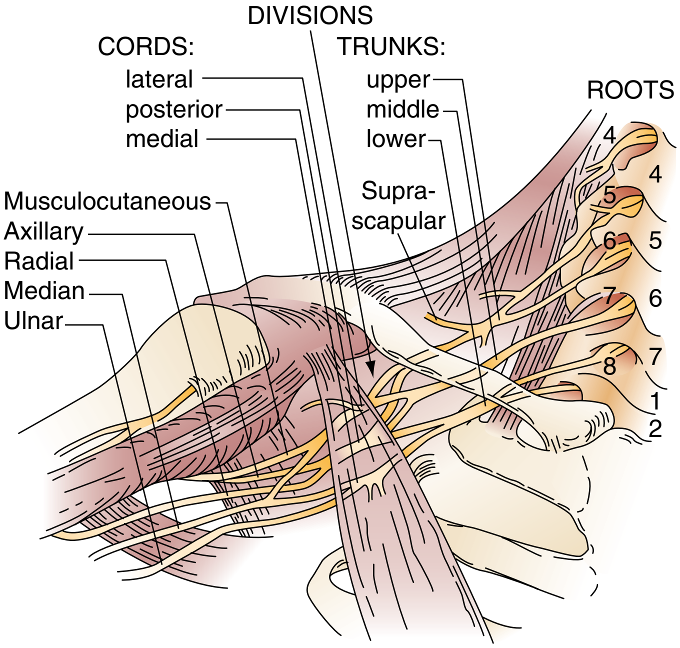

FIGURE 110.28 Detailed view of brachial plexus. (From Urschel HC, Razzuk M. Upper plexus thoracic outlet syndrome: Optimal therapy. *Ann Thorac Surg.* 1997;63:935-939.)

Diagnosis

TOS symptoms vary depending on the neurovascular structure that is compressed as it traverses the thoracic outlet. TOS can result from a combination of developmental abnormalities, injuries, and physical activities that predispose to neurovascular compression, such as presence of a cervical rib articulating with the first thoracic rib, supernumerary scalene muscles, or chronic inflammatory change resulting from repetitive trauma. Neurogenic manifestations are reported in more than 90% of cases. Symptoms of subclavian artery compression include hand/arm fatigue, weakness, pallor, claudication, and paresthesia. Thrombosis with distal embolization can rarely occur, producing ischemic changes in the hand. Venous TOS is characterized by upper extremity edema, cyanosis, and effort-induced thrombosis, also known as *Paget-Schroetter syndrome.*

The diagnosis of neurogenic TOS is initially made clinically, but chest and cervical spine films can help identify a potential cervical rib. CT and MRI are helpful to rule out narrowing of the intervertebral foramina, degenerative changes to the spine, or cervical disc pathology. Duplex or Doppler ultrasonography, CT, or angiography/venography may be used to evaluate the arterial and venous system. Electrophysiologic evaluation is indicated for neurogenic TOS to localize areas of abnormal nerve conduction and rule out other compressive syndromes, such as carpal tunnel. Abnormal ultrasound findings in a patient with a suggestive clinical history and no risk factors for atherosclerosis support a diagnosis of arterial TOS.

Positional maneuvers to evaluate a patient with suspected TOS can be easily performed in the clinic to identify the loss or

TABLE 110.5 Overview of the Clinical Presentation, Treatment Strategies, and Prognosis for Thoracic Outlet Syndrome (TOS)

TYPES OF TOS	NEUROGENIC (MOST COMMON FORM OF TOS)	VENOUS INVOLVEMENT OF THE SUBCLAVIAN VEIN	ARTERIAL INVOLVEMENT OF THE SUBCLAVIAN ARTERY
Sex	More common in females (3.5:1)	More common in males	Females and males equally
Typical age	20–40 years	20–30 years	20–30 years
Risk factors	• Repetitive movements • Previous trauma	• Strenuous work using arms • Athletics	• Vigorous arm activity
Symptoms	• Pain down arm, forearm, ring finger, and little finger • Tingling/numbness at night • Arm/hand weakness • Arm/hand swelling • Loss of dexterity • Cold intolerance • Headache	• Pain in affected arm, often associated with strenuous work • Arm/hand swelling • Veins of shoulder and chest appear more visible • Hand/arm appears blue in color • Blood clot (DVT) may develop	• Pain at rest • Pain with arm activity • Hand appears white in color • Hand/arm cool • Decreased pulse • Aneurysm of subclavian artery may be present • Thrombosis (blood clot) may develop
Lab studies	None	Coagulation studies if DVT develops	Coagulation studies if blood clot develops
Imaging studies	Chest x-ray	Chest x-ray Ultrasound Venography or angiography	Chest x-ray Ultrasound Angiography
Other studies	Nerve conduction study	Nerve conduction study	Nerve conduction study
Treatment	• Physical therapy (PT) • Lidocaine blocks • Botox injections • Surgical intervention • Post-op PT • Medication	• Anticoagulation (if DVT develops) • Surgical intervention • Venogram/venoplasty • Post-op PT	• Anticoagulation (if blood clot or thrombosis develops) • Surgical intervention • Angiogram/angioplasty • Post-op PT
Prognosis	Good	Good	Good

DVT, Deep vein thrombosis.

decrease of radial pulse or reproduce neurologic symptoms. Evocative tests to illicit symptoms include (Fig. 110.29):

- Adson (scalene) test. The patient inspires maximally and holds their breath with the neck fully extended, and the head is turned toward the affected side. This maneuver narrows the space between the scalenus anticus and medius, resulting in compression of the subclavian artery and the brachial plexus. Decrease or loss of the ipsilateral radial pulse suggests compression.
- Halsted (costoclavicular) test. The patient is instructed to place their shoulders in a military position (drawn backward and downward) to narrow the costoclavicular space between the first rib and the clavicle, causing neurovascular compression. Reproduction of neurologic symptoms or decrease or loss of the ipsilateral radial pulse suggests compression.
- Wright (hyperabduction) test. The patient's arm is hyperabducted 180 degrees, which causes the neurovascular structures to be compressed in the subcoracoid region by the pectoralis tendon, the head of the humerus, or the coracoid process. Decrease or loss of ipsilateral radial pulse suggests compression.
- Roos test. The patient abducts the involved arm 90 degrees with external rotation of the shoulder. Maintaining this body position, the patient opens and closes their hand rapidly for 3 minutes to reproduce symptoms. Additionally, neurogenic compromise may be detected using provocative tests, such as percussion of the nerve (Tinel sign) or flexion of the elbow or wrist (Phalen sign).

Management

Neurogenic TOS should initially be managed with physical therapy. Indications for surgical intervention include failure of conservative management, progressive neurologic symptoms, prolonged ulnar or median nerve conduction velocities, narrowing or occlusion of the subclavian artery, thrombosis of the axillary or subclavian vein, symptoms of thromboembolism, or acute limb ischemia. The goal of surgery is to release the narrowing or pressure point at the thoracic outlet. This is achieved in most cases by detachment of the anterior and middle scalene muscle from the first rib and by resection of the rib (in the presence of an accessory rib, it is resected). Additional interventions may include release of the pectorals minor muscle from its insertion on the coracoid process and neurolysis of dense fibrosis along the brachial plexus. Identification and preservation of the brachial plexus, phrenic nerve, long thoracic nerve, and subclavian vessels are critical during surgery. For patients with venous thrombosis, thrombolysis and thoracic outlet decompression are performed. For patients with acute arterial ischemia resulting from distal embolization, thrombolysis or embolectomy may be required in conjunction with surgical repair (with possible arterial reconstruction) and thoracic outlet decompression. When indicated, surgery is beneficial in most patients with TOS, and long-term functional outcome of surgical treatment is satisfactory. Recurrent symptoms may prompt reoperation in up to one-third of patients.[50]

PLEURA

Pleural Effusions

The pleural space is a potential space defined by a small amount of lubricating fluid separating the visceral (lining the outer surface of the lung) and parietal (lining the inner surface of the chest wall) pleura. Several benign and malignant etiologies can disrupt the balance of fluid production and absorption, leading to the development of a pleural effusion, or the accumulation of fluid in between the parietal and visceral pleura (Box 110.3). Pleural fluid can be identified on CXR as the presence of 300 mL of fluid, causing blunting of the costophrenic angle on an upright posteroanterior view.

The movement of fluid across the pleural membranes is governed by Starling's law of capillary exchange. The amount of pleural fluid is controlled by a balance of oncotic and hydrostatic pressure within the pleural space and the pleural capillaries. In normal physiology, the net pressure moves fluid from the parietal pleura into the pleural space, and pleural fluid is reabsorbed through lymphatics. An imbalance of accumulation and absorption can lead to the development of a pleural effusion. The causative factors for pleural fluid accumulation include increased hydrostatic pressure, decreased pleural pressure, increased capillary permeability, decreased plasma oncotic pressure, and decreased lymphatic drainage.

Pleural fluid is characterized as being either transudative or exudative based on the mechanism for fluid accumulation and pleural fluid chemistry. Transudative effusions are protein-poor and result from increased hydrostatic pressure or decreased plasma oncotic pressure. Common causes of transudative effusions include congestive heart failure, nephrotic syndrome, cirrhosis, and hypoalbuminemia. In contrast, exudative effusions are protein-rich and are

BOX 110.3 Pleural Effusions

Cause of Transudative Effusions

- Congestive heart failure
- Cirrhosis
- Nephrotic syndrome
- Hypoalbuminemia
- Fluid retention or overload
- Pulmonary embolism
- Lobar collapse
- Meigs syndrome

Cause of Exudative Effusions

- Malignant
  - Primary lung or metastatic carcinoma
  - Lymphoma
  - Mesothelioma
- Infectious
  - Bacterial (parapneumonic) or empyema
  - Tuberculosis

  - Sarcoidosis
  - After coronary artery bypass grafting
  - Radiation/trauma
  - Dressler syndrome
  - Pulmonary embolism with infarction
  - Asbestosis related

related to local inflammatory factors that precipitate pleural fluid accumulation. Common causes of exudative effusions are infection, malignancy, granulomatous diseases, and other inflammatory states. After thoracentesis, pleural fluid can be analyzed for chemical, microbiologic, and cellular content to determine the type of pleural effusion present. Based on Light's criteria, exudative effusions will have at least one of the following characteristics: (1) ratio of pleural fluid protein to serum protein of greater than 0.5, (2) ratio of pleural fluid lactate dehydrogenase (LDH) to serum LDH of greater than 0.6, or (3) pleural fluid LDH greater than 0.67 of the upper limits of normal serum LDH. Pleural fluid analysis typically includes gross inspection, cell counts and differential, total protein, pH, LDH, glucose, and cholesterol. Fluid culture (for aerobic, anaerobic, and fungal organisms), Gram stain, and cytology can also be performed if infection or malignancy are suspected. After the etiology of pleural effusion is determined, successful definitive management involves treatment of the underlying cause.

Benign Pleural Effusions

Most benign pleural effusions are transudative, free flowing, and without loculations. Initial treatment of symptomatic pleural effusions involves treating the primary etiology and draining the effusion via thoracentesis or thoracostomy tube placement. Asymptomatic effusions are typically not drained. Uncomplicated parapneumonic effusions that are small and without evidence of infection generally resolve with antibiotics alone and do not require drainage. For larger or complicated parapneumonic effusions (e.g., with microbiologic or biochemical evidence of infection), drainage is recommended in addition to antibiotics. After drainage, radiographic evidence of complete lung reexpansion should be sought. Failure of the lung to expand completely may suggest development of a "trapped lung" from formation of a fibrous peel that encases the visceral pleura, which may require decortication if symptoms persist. Chronic sterile effusions can be treated with an indwelling pleural catheter insertion, which can result in pleural symphysis. However, when used for heart or renal failure, great care is needed to manage fluid and electrolyte shifts.

Malignant Pleural Effusion

Approximately 15% of all cancer patients develop MPEs from malignant cells infiltrating the pleural space.[51] The median survival of patients with MPEs is 5 months.[52] Pleural biopsy and cytology can aid with diagnosis. MPE treatment is aimed at symptom relief and palliation because it typically indicates advanced-stage cancer and a poor overall prognosis. Drainage is recommended for large-volume, symptomatic MPEs (Fig. 110.30). For recurrent MPEs, insertion of an indwelling pleural catheter can be considered because these devices permit frequent drainage of pleural fluid and can induce pleurodesis. Chemical pleurodesis via a thoracostomy tube or VATS is another reasonable treatment option. Pleurectomy and pleurodesis are reserved for patients who fail other therapies and have a reasonable life expectancy.

Empyema

An empyema is a collection of purulent fluid within the pleural space, which results from invasion of pyogenic bacteria, fungi, parasites, or mycobacteria. Microorganisms may originate from an adjacent pneumonia, direct inoculation (e.g., penetrating trauma), or another source (e.g., esophageal rupture, bronchogenic carcinoma). Empyemas progress from an acute phase with fluid that is thin and can be drained completely with a pigtail catheter or chest tube to fluid that is increasingly turbid, thicker, and loculated. Mucopurulent debris occurs within the pleural space and compresses the underlying lung parenchyma. The organizing or chronic phase is reflected by lung entrapment with capillary ingrowth and development of a fibrinous pleural covering, which can encase the lung and hinder full reexpansion ("trapped lung").

An empyema typically occurs after a reactive pleural effusion as a consequence of a lung infection. Common causative organisms include gram-negative, anaerobic, streptococcal, and pneumococcal bacteria. Mycobacterial infection can also cause empyema formation and should be considered in patients who live in an endemic area and/or have specific risk factors. Empyemas can also form after trauma or surgery (e.g., bronchopleural fistula) or esophageal perforation. Symptoms typically include constitutional symptoms of general malaise, fever, loss of appetite, and weight loss. Evaluation includes CXR and CT scan.

Treatment depends on the disease severity, location, and duration of infection. Drainage and antibiotics are required. Drainage of early

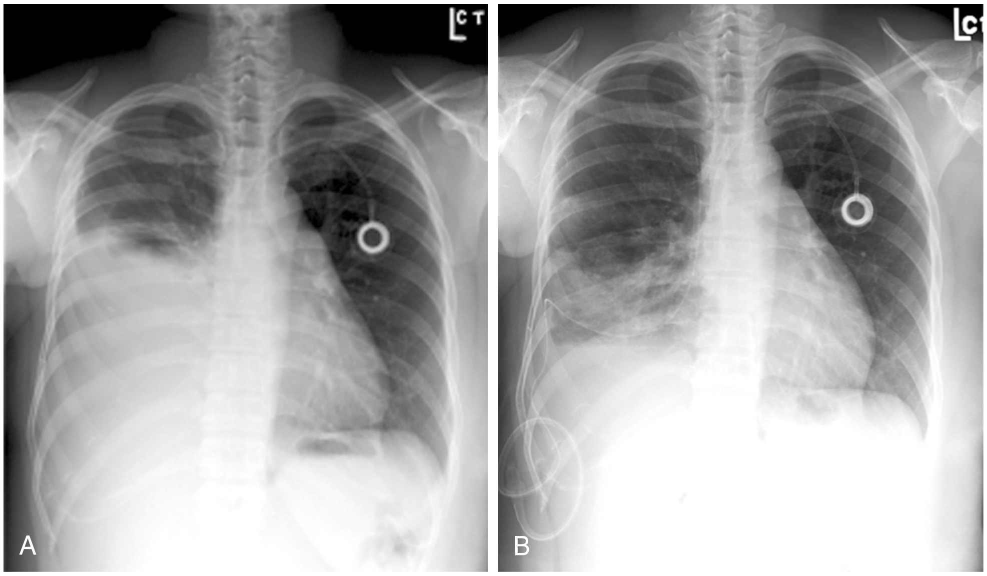

FIGURE 110.30 (A) Malignant pleural effusion causing dyspnea. A long-term indwelling pleural catheter was placed as an outpatient procedure to facilitate drainage at home to prevent dyspnea. Hospitalization was not required. (B) After drainage. A long-term indwelling pleural catheter is effective in patients with trapped lung. Every-other-day drainage reduces impairment of the contralateral lung and prevents mediastinal shift.

empyemas in the purulent phase can often be achieved by insertion of a pleural drain (pigtail catheter or chest tube). With complex, loculated effusions, surgery is usually indicated. Chest tubes can generally be removed when the daily drainage volume falls below 100 to 200 mL, imaging shows reduction in the size of the effusion, and the patient has resolving clinical signs of infection. Early VATS for complex effusions has been shown to reduce hospital length of stay and provide good lung expansion. Use of fibrinolytic agents, such as intrapleural tissue plasminogen activator and DNase, may aid with catheter drainage and reduce the need for surgical drainage. However, they are not recommended for routine use of complicated empyemas because they are expensive and less effective than commonly believed.[53] For organized empyemas with a thick peel, thoracotomy and decortication remain a common treatment to adequately reexpand the lung and clean out the pleural space.

Chylothorax

Chylothorax occurs when chyle from the thoracic duct empties into the pleural space. Chyle is a milky-appearing, white fluid containing a high concentration of triglycerides, chylomicrons, and white blood cells. Chylothorax can result from multiple etiologies (Box 110.4). Because of the nutritional consequences of a chyle leak (e.g., loss of fat and protein) and the volume of the leak (0.5–3.0 L/day), fluid and nutritional replacement and correction of the underlying problem are necessary. An untreated chylothorax is associated with significant morbidity and mortality. The diagnosis can be made with thoracentesis or drainage with a thoracostomy tube. Pleural fluid analysis typically demonstrates lymphocyte predominance, low LDH, high concentration of triglycerides ($>$110 mg/dL), and a cholesterol level $<$200 mg/dL. Initial management strategies for low-output chylothorax ($<$500 cc of chyle/day) include drainage for symptom control, bowel rest, and parenteral nutrition. High-output chylothorax ($>$1 L per day) requires early definitive intervention (e.g., ligation of the thoracic duct or percutaneous thoracic duct embolization). Adjuncts to these treatment strategies include a diet with medium-chain triglycerides and/or administration of octreotide. Surgical ligation of the thoracic duct commonly occurs via the right chest, where it enters the chest through the diaphragmatic hiatus. At the time of surgical repair, placement of olive oil or ice cream through a nasogastric tube may increase chyle drainage into the operative field and help identify the area of thoracic duct disruption. However, a minimally invasive or open thoracic duct ligation encompasses all the tissue between the aorta, esophagus, spine, and azygous vein.

BOX 110.4 Chylothorax

- Traumatic (chest and neck)
  - Blunt
  - Penetrating
- Iatrogenic
  - Catheterization, particularly subclavian vein
  - Postsurgical

- Neoplasms
  - Lymphoma, lung, esophageal, or mediastinal neoplasms
  - Metastatic carcinoma
- Infectious
  - Tuberculous lymphadenosis
  - Mediastinitis
  - Ascending lymphangitis
- Other
  - Lymphangioleiomyomatosis
  - Venous thrombosis
  - Congenital

Pneumothorax

Pneumothorax is the accumulation of air within the pleural space. It can occur after trauma, surgery, central line insertion, increased pressure from mechanical ventilation, or as a sequela of underlying pulmonary disease (e.g., COPD, CF) or other conditions (e.g., catamenial pneumothorax) (Box 110.5). A primary spontaneous pneumothorax generally occurs as a result of small apical subpleural blebs or bullae (air sacs between the lung tissue and pleura) that rupture into the pleural cavity. A tension pneumothorax occurs when air continues to enter the pleural space without decompression, leading to mediastinal compression and shift and a decrease in ventilation and venous return. Cardiopulmonary collapse and death can ensue. Immediate decompression with needle or tube thoracostomy can be lifesaving.

A primary spontaneous pneumothorax typically presents with pain and dyspnea in tall and thin young males. Tobacco use is a significant risk factor. CT can be performed to assess for the etiology or the presence of other occult lung disease. On examination, breath sounds are usually absent over the affected hemithorax, and subcutaneous emphysema may be present. Treatment depends on the size of the pneumothorax and the presence of symptoms or mediastinal shift. A small pneumothorax (≤3 cm at apex or ≤2 cm at hilum) may be followed and resolve spontaneously. Larger or enlarging pneumothoraxes require aspiration or placement of a tube thoracostomy. After chest tube placement, patients should receive a daily CXR until lung reexpansion and cessation of air leak. Persistent air leak (>2 days) or failure of the lung to expand fully may indicate the need for surgical intervention. Surgery is recommended for patients who have a persistent or recurrent pneumothorax, develop another episode, or work in high-risk professions (e.g., divers, pilots). Surgery typically involves VATS resection of blebs with pleurodesis.

Mesothelioma

Malignant pleural mesothelioma (MPM) is an aggressive malignancy with a poor prognosis (median survival: 9–17 months) that arises from the mesothelial cells lining the parietal and visceral pleura.[54,55] MPM pathogenesis is tightly linked to asbestos exposure, and a long latency period (15–40 years) exists between primary exposure and disease development. Because of the insidious onset of symptoms, the majority of patients are diagnosed with advanced disease. Histologic subtypes include epithelial (most favorable prognosis), sarcomatoid, and biphasic histology. Symptoms include shortness of breath, cough, pleural effusion, weight loss, chest pain, and fever. Imaging can reveal unilateral pleural thickening and pleural effusion. Diagnosis can be made with pleural biopsy.

BOX 110.5 Pneumothorax

  Blunt
Iatrogenic
  Mechanical ventilation
  Needle puncture: thoracentesis, fine-needle aspiration lung nodule, central line insertion
  Postsurgical

For functionally fit patients with epithelioid MPM limited to one hemithorax, a multimodal treatment strategy may be considered that involves chemotherapy, macroscopic complete resection (MCR; R0 or R1 resection), and radiation therapy. MCR can be achieved either by extrapleural pneumonectomy (EPP; resection of the entire lung, including the visceral and parietal pleura and the diaphragm ± pericardium through a large posterolateral thoracotomy) or by extended pleurectomy and decortication (EPD; resection of the parietal and visceral pleura and the diaphragm ± pericardium while preserving the lung parenchyma through a large posterolateral thoracotomy). EPP is the most extensive surgery for MPM and is associated with high rates of mortality (5%–20%) and morbidity (40%–60%). EPD is a lung-preserving surgery that offers somewhat of a less extensive resection; however, it is associated with less mortality, less morbidity, and a comparable survival to EPP.[56] For patients with sarcomatoid type, patients with advanced disease, or those deemed poor surgical candidates, treatment includes systemic chemotherapy, palliative radiation therapy, and management of local symptoms from any MPE.

Solitary Fibrous Tumor of the Pleura

Solitary fibrous tumors are rare fibroblastic mesenchymal tumors that arise either from the visceral or parietal pleura. They rarely metastasize. These tumors often attach to the pleura with a thin pedicle and may grow quite large. Symptoms are often related to mass effect, and up to 20% are associated with digital clubbing and hypertrophic pulmonary osteoarthropathy (Pierre-Marie-Bamberger syndrome). Treatment for localized disease consists of complete en bloc resection of the tumor, its pedicle, and the pleura/lung at the base of the pedicle. Wedge resection is sufficient in most cases to remove the pedicle and other adhesions of the tumors to the lung. Long-term postoperative surveillance is indicated because these tumors can recur locally.

MEDIASTINUM

Mediastinal abnormalities may present as an asymptomatic mass identified on imaging or with significant symptoms resulting from mass effect on adjacent structures, including hypoxia, facial swelling, dysphagia, and respiratory distress. CT or MRI can assist with characterization of mediastinal masses. Biopsy specimens may be needed to make the diagnosis. Mediastinal masses differ between adults and children. The most common mediastinal masses in adults are thymomas and thymic cysts, neurogenic tumors, other cysts, germ cell tumors, and lymphomas (Box 110.6). In children, the most common pathologies are neurogenic tumors, germ cell tumors, primary cysts, and lymphomas. Malignant neoplasms account for 25% to 50% of mediastinal masses in adults. Lymphomas, thymomas, germ cell tumors, primary carcinomas, and neurogenic tumors are the most common. Many mediastinal lesions occur in characteristic sites within the mediastinum (Fig. 110.31). Approximately half of all mediastinal masses

BOX 110.6 Mediastinum: Classification of Primary Mediastinal Tumors and Cysts

- Thymoma
  - Thymic carcinoma
- Lymphoma
  - Hodgkin disease
  - Lymphoblastic lymphoma
  - Large cell lymphoma
- Germ cell tumors
  - Teratodermoid (benign/malignant)
  - Seminoma
  - Nonseminoma
    - Embryonal
    - Choriocarcinoma
    - Endodermal
- Primary carcinomas
  - Mesenchymal tumors
    - Fibroma/fibrosarcoma
    - Lipoma/liposarcoma
    - Leiomyoma/leiomyosarcoma
    - Rhabdosarcoma
    - Xanthogranuloma
    - Myxoma
    - Mesothelioma
    - Hemangioma
    - Hemangioendothelioma
    - Hemangiopericytoma
    - Lymphangioma
    - Lymphangiomyoma
    - Lymphangiopericytoma
  - Endocrine tumors
    - Intrathoracic thyroid
    - Parathyroid adenoma/carcinoma
    - Carcinoid
- Cysts
  - Bronchogenic
  - Pericardial
  - Enteric
  - Thymic
  - Thoracic duct
  - Nonspecific
- Giant lymph node hyperplasia
  - Castleman disease
- Chondroma

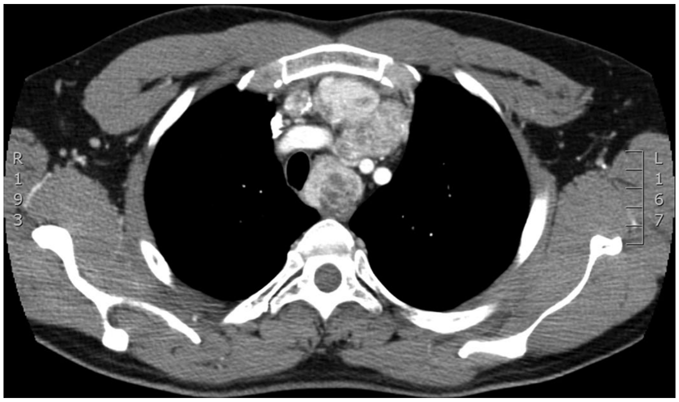

FIGURE 110.32 Thyroid carcinoma within the mediastinum. The tumor was resected via median sternotomy. No invasion was identified. A complete resection was accomplished.

are located in the anterosuperior mediastinum, with the remainder occurring in the posterior or middle mediastinum.

Anterosuperior Compartment

The anterosuperior compartment of the mediastinum borders the undersurface of the sternum ventrally, the pericardium dorsally, and the visceral pleura laterally (at the apposition of the pleura and pericardium). Among adults >40 years old, thymomas are the most common neoplasm of the anterior mediastinum, and the second most common pathology is retrosternal goiter. Other pathologies are lymphomas, seminomas, nonseminoma germ cell tumors, and teratomas. Between the ages of 10 and 40 years old, lymphomas and teratomas in females and lymphomas, seminomas, nonseminoma germ cell tumors, and teratomas in males are the most frequently occurring neoplasms. In children, lymphomas and teratomas are the common neoplasms of the anterior mediastinum. Additional pathologies of the anterior mediastinum include carcinoid tumors, which may be found within the thymus, and primary carcinomas of the mediastinum, which are often unresectable and respond poorly to treatment (Fig. 110.32).

Middle Compartment

The middle compartment extends from (and contains) the structures of the thoracic inlet (superiorly) to the pericardium anteriorly and to the anterior surface of the vertebrae posteriorly.

Lymphomas can occur in the middle mediastinum. Tumors of the heart, trachea, mainstem bronchi, and esophagus can also form. Benign diseases, such as pericardial cysts and bronchogenic cysts, also occur here. Vascular masses and enlargement may represent aortic pathologies such as aortic aneurysm, abscess, or dissection.

Posterior or Paravertebral Sulci Compartment

The posterior compartment is bounded by the middle compartment anteriorly and the costophrenic angle laterally. Neurogenic tumors are usually the most common primary tumors of the mediastinum, and about 25% of these tumors are malignant. These tumors are located within the paravertebral sulcus and may erode the adjacent vertebra or rib. Schwannomas, or neurilemomas, are the most common neurogenic tumors. Neurofibromas arise from the nerve sheath and fibers and occur in middle-aged patients. In children, ganglioneuroma is the most common neurogenic tumor. Surgical resection of neurogenic tumors is usually indicated.

Embryologic development of the neural crest cells forms the basis of NETs in the mediastinum. Of pheochromocytomas, 1% occur within the mediastinum. Chemodectomas or paragangliomas may arise from chemoreceptor tissues around the aorta and great vessels, including the carotid. Symptoms may result from catecholamine production and are alleviated by surgical resection.

Clinical Manifestations and Diagnosis

Symptoms from a mediastinal mass may vary widely and relate to size (e.g., fatigue, weight loss); location; extent of compression or invasion of mediastinal structures; and production of hormones, markers, or other biochemical materials (e.g., myasthenia gravis, fatigue, night sweats). Benign lesions are more often asymptomatic. Specific clinical syndromes may occur as a result of mediastinal tumors. Superior vena cava syndrome (obstruction of the superior vena cava with head and neck and upper extremity swelling), cough, hoarseness (from involvement of the recurrent laryngeal nerve), dyspnea from tumor volume or phrenic nerve paralysis, and dysphagia can occur with compression or invasion of mediastinal structures. Other manifestations include Horner syndrome (characterized by ptosis, miosis, anhidrosis) and Pancoast syndrome. Postobstructive pneumonitis or infection of benign pericardial or enteric duplication cysts may produce fever or sepsis. Myasthenia gravis can result from thymomas. Mediastinal Hodgkin disease may produce an intermittent fever. Patients with hypertension from pheochromocytoma, thyrotoxicosis from goiter, hypercalcemia from ectopic mediastinal parathyroid adenoma or carcinoma, or hypogammaglobulinemia should be evaluated carefully.

Evaluation and Diagnostic Imaging

Based on imaging, a differential diagnosis may be obtained based on the location of the mass within the mediastinum. CT scans have replaced plain CXRs as the diagnostic imaging of choice for mediastinal masses. MRI can be used if invasion into specific anatomic structures in the mediastinum is in question. For instance, an anterior mediastinal mass, such as a thymoma, can be evaluated for the extent of compression or possible invasion into the pulmonary artery, innominate vein, or superior vena cava. Similarly, posterior mediastinal masses can be evaluated by MRI for the extent of invasion into the brachial plexus, great vessels, vertebral body, and neural foramina. Echocardiography may identify pericardial and cardiac involvement. Additional imaging techniques may be used in specific scenarios (technetium scan for ectopic thyroid tissue or a substernal goiter and 131-I metaiodobenzylguanidine for pheochromocytoma).

Mediastinal tumors may secrete specific hormones or biologic markers. Parathyroid adenomas or functioning parathyroid carcinomas may secrete parathyroid hormone. Pheochromocytomas may secrete catecholamines, which may cause hypertension. Carcinomas may secrete carcinoembryonic antigen. Nonseminomatous germ cell neoplasms may secrete α-fetoprotein (AFP) or β-human chorionic gonadotropin (β-HCG). Lymphomas may be associated with elevated levels of LDH and alkaline phosphatase. Thymomas may be associated with production of anti-acetylcholine receptor (AChR) antibodies. Skin tests for tuberculosis, histoplasmosis, and coccidioidomycosis may also yield positive results.

Histologic Diagnosis

Radiographic diagnosis may be sufficient for the design of a treatment plan for mediastinal cysts and other solid lesions that are clearly resectable (e.g., early stage thymoma). However, a tissue specimen for definitive diagnosis is required for the workup of more complex solid masses. Fine-needle aspiration or needle biopsy may provide sufficient tissue for diagnosis of thymic carcinoma or other defined neoplasms. For lymphomas, thymomas, and neural tumors, larger amounts of tissue may be required for cellular analysis. In these patients, core-needle biopsy, mediastinoscopy, or intrathoracic biopsy (via thoracoscopy or thoracotomy) may be considered. When resection is considered, median sternotomy provides a direct visual approach to the anterior and middle mediastinum. Thoracotomy provides a direct visual approach to the posterior mediastinum. Minimally invasive resection techniques are becoming increasingly used for treatment of noninvasive tumors.

PRIMARY MEDIASTINAL CYSTS

Primary mediastinal cysts are characterized by the organ of origin and may be bronchogenic, pericardial, enteric, thymic, or of an unspecified nature. Most cases are asymptomatic; however, these cysts may cause mass effect on vital structures within the mediastinum with increasing size. Benign cysts may be resected minimally invasively.

Bronchogenic cysts account for most primary cysts of the mediastinum. They originate as sequestrations from the ventral foregut and can be situated within the lung parenchyma or the mediastinum. Bronchogenic cysts are usually located proximal to the trachea or bronchi and may be posterior to the carina. A connection to the bronchus rarely exists; however, when it occurs, these cysts may become infected. Diagnostic imaging may reveal an air-fluid level within the mediastinum. Two-thirds of bronchogenic cysts are asymptomatic. In infants, cysts can cause respiratory compromise by compressing the trachea or the bronchus. Resection is recommended.

Pericardial cysts are the second most common and occur in the cardiophrenic angle, typically on the right side. These cysts can communicate with the pericardium. Typically, clear fluid is encountered. The typical characteristics of pericardial cysts include location in the cardiophrenic angle, characteristic appearance, smooth borders, and attenuation approximating water for the cyst fluid. Needle aspiration and routine surveillance may be all that is needed. However, resection may be used for diagnosis and to exclude malignant tumors.

Enteric cysts or duplication cysts arise from the primitive foregut, which develops into the upper division of the gastrointestinal tract. These cysts are usually attached to the esophagus. Symptoms such as dysphagia can occur with compression of the esophagus. Neuroenteric cysts are associated with anomalies of the vertebral column. Excision is recommended, and a small part of the cyst bordering the esophagus may be left in place (2–3 cm), with the mucosa cauterized to prevent fluid secretion and recurrence.

PRIMARY MEDIASTINAL NEOPLASMS

Thymoma

Thymomas are the most common neoplasm of the anterosuperior mediastinum and are considered malignant tumors. The major histologic subtypes are A (most indolent), AB, and B1 to B3 (most aggressive) thymomas. Thymic carcinomas are more aggressive than thymomas and are separately classified. The peak incidence is in the third through fifth decades of life. A thymoma may appear on a radiograph as a small, well-circumscribed mass or as a bulky, lobulated mass confluent with adjacent mediastinal structures (Fig. 110.33). Symptoms are related to local mass effect, causing chest pain, dyspnea, hemoptysis, cough, and superior vena cava syndrome or systemic syndromes caused by immunologic mechanisms. The most common syndrome is myasthenia gravis (occurs in ~40% of cases). Other paraneoplastic syndromes include pure red cell aplasia, hypogammaglobulinemia, and thymoma-associated multiorgan autoimmunity. Staging of thymomas and thymic carcinomas is based on the extent of the primary tumor and the presence of invasion into adjacent structures and/or dissemination. Until recently, thymomas were staged according to the modified Masaoka-Koga classification system; however, a formal TNM-based staging system for thymic tumors has been issued by the AJCC as part of its 8th edition cancer staging manual (Table 110.6).

Thymomas may be viewed as resectable, potentially resectable, and unresectable. Patients presenting with small, fully encapsulated thymomas should undergo surgery. For patients with invasive but potentially resectable tumors, neoadjuvant and adjuvant chemotherapy, radiation, and immunotherapy are applied in conjunction with surgery to achieve complete or at least macroscopically complete tumor resection. Resection and reconstruction of involved mediastinal structures, including the superior vena cava and innominate vein, as well as resection of droplet metastatic lesions, may achieve significant prolongation of survival in select patients.

TABLE 110.6 Thymoma Staging

T DESCRIPTORS

CATEGORY	DEFINITION (INVOLVEMENT OF)[a,b]
T1	
a	Encapsulated or unencapsulated, with or without extension into mediastinal fat
b	Extension into mediastinal pleura
T2	Pericardium
T3	Lung, brachiocephalic vein, superior vena cava, chest wall, phrenic nerve, hilar (extrapericardial) pulmonary vessels
T4	Aorta, arch vessels, main pulmonary artery, myocardium, trachea, or esophagus

N AND M DESCRIPTORS

CATEGORY	DEFINITION (INVOLVEMENT OF)[a]
N0	No nodal involvement
N1	Anterior (perithymic) nodes
N2	Deep intrathoracic or cervical nodes
M0	No metastatic pleural, pericardial, or distant sites
M1	
A	Separate pleural or pericardial nodule(s)
B	Pulmonary intraparenchymal nodule or distant organ metastasis

STAGE GROUPING

STAGE	T	N	M
I	T1	N0	M0
II	T2	N0	M0
IIIa	T3	N0	M0
IIIb	T4	N0	M0
IVa	T any	N1	M0
	T any	N0,1	M1a
IVb	T any	N2	M0,1a
	T any	N any	M1b

[a] Involvement must be pathologically proven in pathologic staging.
[b] A tumor is classified according to the highest T level of involvement that is present with or without any invasion of structures of lower T levels.
From Detterbeck FC, Stratton K, Giroux D, et al. The IASLC/ITMIG thymic epithelial tumors staging project: proposal for an evidence-based stage classification system for the forthcoming (8th) edition of the TNM classification of malignant tumors. *J Thorac Oncol.* 2014;9:S65-S72.

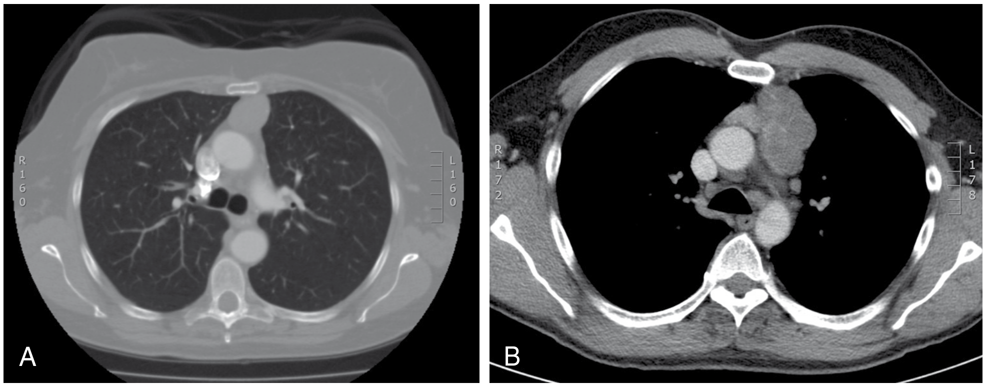

FIGURE 110.33 (A) Computed tomography (CT) scan of the chest in a patient with myasthenia gravis and thymoma. The thymoma is small, with a plane of separation between the tumor and the pericardium. (B) Chest CT scan in a patient with a larger mediastinal mass. The location, character, and size are noted. Transthoracic core-needle biopsy was performed. Germ cell tumor markers were normal. Pathology demonstrated thymoma. A 6.5-cm thymoma was subsequently resected. There was no invasion of the pericardium. A complete resection (R0) was accomplished.

For patients with myasthenia gravis and a thymoma, surgery is advocated as soon as the patient's degree of weakness is sufficiently controlled to permit surgery. Only 10% to 15% of patients with myasthenia gravis have a thymoma, whereas 40% of patients with a thymoma have myasthenia. Attentive perioperative management in these patients is crucial to prevent complications. Anticholinesterase inhibitors, plasmapheresis, and/or intravenous immunoglobulin are used pre- and postoperatively to control generalized weakness. Intensive pulmonary toilet, early extubation, chest physiotherapy, and avoidance of paralyzing agents and narcotics help ensure safe recovery from surgery. During surgery, complete resection of the thymus and all accessible mediastinal fatty areolar tissue is performed to ensure removal of all ectopic thymic tissue and reduce risk of tumor recurrence. Preservation of the phrenic nerves is an integral component of thymectomy. Improvement in myasthenia gravis symptoms and reduction in the dosages of drugs required to control the disease are anticipated to a certain extent in the months after surgery.[57]

Germ Cell Tumors

Germ cell tumors arise from primordial germ cells that fail to complete the migration from the urogenital ridge and rest in the mediastinum. Treatment depends on tumor histology. The anterosuperior mediastinum is the most common extragonadal primary site of these tumors. These lesions are histologically identical to germ cell tumors originating in the gonads. The testes of a male patient with a mediastinal germ cell tumor should be carefully examined and imaged with ultrasonography. Biopsy is reserved for positive findings.

Teratomas

Teratomas are the most common mediastinal germ cell neoplasms and are most frequently located in the anterosuperior mediastinum. They are composed of multiple tissue elements that are derived from the three primitive embryonic layers (ectoderm, mesoderm, and endoderm). The peak incidence occurs in the second and third decades of life. Radiographic evidence of normal tissue (e.g., well-formed teeth or globular calcifications) in an abnormal location can be considered specific. The teratodermoid (dermoid) cyst is the simplest form of teratoma and is composed of derivatives of the epidermal layer, including dermal and epidermal glands, hair, and sebaceous material. The solid component of the tumor often contains well-differentiated elements of bone, cartilage, teeth, muscle, connective tissue, fibrous and lymphoid tissue, nerve, thymus, mucous and salivary glands, lung, liver, or pancreas. Malignant tumors are differentiated from benign tumors by the presence of primitive (embryonic) tissue or by the presence of malignant components. Immature teratomas contain combinations of mature epithelial and connective tissues with immature areas of mesenchymal and neuroectodermal tissues. In contrast, mature teratomas contain well-differentiated histologic elements derived from at least two embryonic cell layers.

Diagnosis and therapy rely on surgical excision, most commonly through a median sternotomy or posterolateral thoracotomy, depending on tumor location. Patients with mature teratomas are treated with surgical resection because these tumors are generally insensitive to chemotherapy and radiation therapy. For malignant teratomas, chemoradiation combined with surgical excision is individualized for the type of malignant components contained in the tumors. The overall prognosis for malignant mediastinal teratomas is poor.

Malignant Nonteratomatous Germ Cell Tumors

Malignant germ cell tumors occur predominantly in the anterosuperior mediastinum, are more common in males, and are typically diagnosed between the ages of 20 and 40 years. Most patients have symptoms of chest pain, cough, dyspnea, and hemoptysis. Superior vena cava syndrome may also occur. These aggressive tumors are often metastatic at presentation. Serologic measurements of AFP and β-HCG are useful for differentiating seminomas from nonseminomatous tumors, assessing treatment response, and detecting early recurrence. Seminomas frequently produce β-HCG but do not produce AFP; in contrast, nonseminomatous tumors typically secrete one or both hormones. This differentiation is important because seminomas are sensitive to radiation, whereas nonseminomatous tumors are relatively insensitive to radiation.

Seminomas

Seminomas constitute about one-third of malignant mediastinal germ cell tumors. Most seminomas will have evidence of metastasis at the time of diagnosis, most often to the lymph nodes. Symptoms are related to the mass effect of the tumor on adjacent mediastinal and pulmonary structures. Superior vena cava syndrome occurs in 10% to 20% of patients. These tumors are sensitive to irradiation and chemotherapy. Therapy is determined by the stage of the disease. For most patients with seminomas, platinum-based chemotherapy is the primary treatment option. Long-term disease-free survival is about 90% after treatment with chemotherapy.[58] Radiation therapy may be considered for patients who do not have bulky or metastatic disease. Cytoreductive resection before chemotherapy or radiation therapy is unnecessary. Infrequently, complete surgical excision is possible for very small and localized tumors.

Nonseminomatous Tumors

Malignant nonseminomatous germ cell tumors include choriocarcinomas, embryonal carcinomas, immature teratomas, teratomas with malignant components, and endodermal cell (yolk sac) tumors and occur mostly in males in their third or fourth decades. Diagnostic imaging reveals a large anterior mediastinal mass with frequent extension to the lung, chest wall, and mediastinal structures. Nonseminomatous germ cell neoplasms are more aggressive tumors and are more frequently disseminated at the time of diagnosis, they are rarely radiosensitive, and more than 90% produce either β-HCG or AFP. All patients with choriocarcinoma and some patients with embryonal cell tumors have elevated levels of β-HCG. AFP is most commonly elevated in patients with embryonal cell carcinomas and yolk sac tumors. Mediastinal nonseminomatous germ cell tumors are associated with the development of hematologic disorders, such as acute megakaryocytic leukemia, systemic mast cell disease, malignant histiocytosis, myelodysplastic syndrome, and idiopathic thrombocytopenia. Treatment involves cisplatin and etoposide-based chemotherapy regimens. Serum markers (i.e., AFP or β-HCG) can be followed to assess response to systemic treatment. Operative intervention may be required for salvage resection after chemotherapy. The pathology of the resected postchemotherapy specimen appears to be the most significant predictor of survival. The presence of residual malignancy after chemotherapy portends a poor prognosis and the need for additional chemotherapy.

Neurogenic Tumors

Neurogenic tumors are usually located in the posterior mediastinum and originate from the sympathetic ganglia (ganglioma, ganglioneuroblastoma, and neuroblastoma), the intercostal nerves (neurofibroma, neurilemoma, and neurosarcoma), and the paraganglia cells (paraganglioma). Although the peak incidence occurs in adults, neurogenic tumors make up a proportionally greater percentage of mediastinal masses in children. Although most neurogenic tumors in adults are benign, a greater percentage of neurogenic tumors are malignant in children. Many of these tumors are asymptomatic.

The most common neurogenic tumor is neurilemoma, or schwannoma, which originates from perineural Schwann cells. They are benign, slow-growing neoplasms that frequently arise from a spinal nerve root but can involve any thoracic nerve. These tumors are well circumscribed and have a defined capsule. They arise from the nerve sheath and extrinsically compress the nerve fibers. About 10% of tumors have extensions into the spinal column and are termed *dumbbell tumors* because of their characteristic shape, with relatively large paraspinal and intraspinal portions connected by an isthmus of tissue traversing the intervertebral foramen. Patients with paraspinal tumors should undergo MRI to evaluate the presence and extent of the tumor, including its relationship to the neural foramen and the intraspinal space. During resection, the intraspinal component should be removed first via a posterior laminectomy. This approach minimizes the potential for spinal column hematoma, cord ischemia, and paralysis. A separate transthoracic approach is needed for resection of the intrathoracic component.

Neuroblastoma

Neuroblastomas originate from the sympathetic nervous system. The most common location for a neuroblastoma is in the retroperitoneum; however, 10% to 20% occur primarily in the mediastinum. These are highly invasive neoplasms that have frequently metastasized before diagnosis. Most of these tumors occur in children 4 years old or younger. A 24-hour urine collection to measure catecholamines should be obtained in children with a posterior mediastinal mass. For most children with low-risk localized tumors, surgical resection alone is usually performed. For those with intermediate-risk neuroblastoma, neoadjuvant chemotherapy with or without surgical resection is often performed. For patients with advanced disease, a multimodal treatment strategy that includes induction chemotherapy, surgical resection, autologous hematopoietic stem cell transplantation, radiation treatment, and maintenance with biologic/immunologic therapy (e.g., dinutuximab) can be used.

Ganglion Tumors

Ganglioneuroblastomas are composed of mature and immature ganglion cells. Treatment of ganglioneuroblastoma ranges from surgical excision alone to various chemotherapeutic strategies, depending on histologic characteristics, age, and stage of disease. Ganglioneuromas are benign tumors that originate from the sympathetic chain and are composed of ganglion cells and nerve fibers. These tumors typically manifest at an early age and are the most common neurogenic tumors occurring during childhood. They usually occur in the paravertebral region. These tumors are well encapsulated and, when cross-sectioned, frequently exhibit areas of cystic degeneration. Surgical excision provides cure.

Paraganglioma (Pheochromocytoma)

Mediastinal paragangliomas are rare tumors, representing less than 1% of all mediastinal tumors and less than 2% of all pheochromocytomas. Although most are found in the paravertebral sulcus, an increasing number occur in the branchial arch structures, coronary and aortopulmonary paraganglia, atria, and islands of tissue in the pericardium. Extraadrenal paragangliomas rarely secrete epinephrine. These tumors are more common in patients with multiple endocrine neoplasia syndromes and Carney syndrome (pulmonary chondroma, gastric leiomyosarcoma, and functioning extraadrenal paraganglioma). In patients who have had excision of an adrenal pheochromocytoma and continue to have symptoms, a search for an extraadrenal lesion should be undertaken, with careful attention to the mediastinum. Tumor localization has improved with CT and iodine-131 metaiodobenzylguanidine scintigraphy. When appropriate, surgical resection is the optimal therapy.

Lymphomas

Although the mediastinum is frequently involved in lymphoma, it is infrequently the sole site of disease at the time of presentation. Patients may have symptoms such as chest pain, cough, dyspnea, hoarseness, and superior vena cava syndrome. Nonspecific systemic symptoms of fever and chills, weight loss, and anorexia can also be noted. Lymphoblastic lymphoma occurs predominantly in children, adolescents, and young adults and represents 60% of cases of mediastinal non-Hodgkin lymphoma.

Surgical excision of all disease is rarely possible. Hence, the surgeon's primary role is to provide sufficient tissue for diagnosis and to assist in pathologic staging. A core-needle biopsy may be unsuccessful because larger tissue samples are needed to make a histologic diagnosis, particularly with nodular sclerosing lesions. A surgical approach may be necessary to obtain sufficient tissue, and the approach depends on the site of disease. It is imperative to biopsy enough tissue and send it fresh to pathology, not fixed in formalin. After treatment, residual radiographic abnormalities within the mediastinum are commonly noted. CT poorly differentiates fibrosis or necrosis from residual tumor. FDG/PET has shown promise as a noninvasive way to detect active mediastinal disease and predict relapse in patients with lymphoma, but tissue confirmation is required.

Endocrine Tumors

Thyroid Tumors

Although substernal extension of a cervical goiter is common, totally intrathoracic thyroid tumors are rare and make up only 1% of all mediastinal masses. These tumors arise from heterotopic thyroid tissue. Although there may be a demonstrable connection with the cervical gland (usually a fibrous connective tissue band), a true intrathoracic thyroid gland derives its blood supply from thoracic vessels. Substernal extensions of a cervical goiter can usually be excised using a cervical approach.

Parathyroid Tumors

Although parathyroid glands may occur in the mediastinum in 10% of patients, they are usually accessible through the cervical incision. Most often, these adenomas are found in the anterosuperior mediastinum (80%) embedded in or near the superior pole of the thymus. This anatomic relationship is the result of the common embryogenesis of the inferior parathyroid glands from the third branchial cleft. The superior parathyroid glands and the lateral lobes of the thyroid gland are derived from the fourth branchial pouch. Because they migrate with the lateral lobes of the thyroid gland to a paraesophageal position, parathyroid adenomas can also be found in the posterior mediastinum.

Most frequently, mediastinal parathyroid adenomas may be excised after a negative exploration of the cervical region through the existing cervical incision. Usually, the vascular supply extends from cervical blood vessels. In patients with persistent hyperparathyroidism after cervical exploration, if localization studies show residual parathyroid in the mediastinum, mediastinal exploration using a median sternotomy or thoracoscopy is indicated.

Parathyroid carcinomas have been reported and are usually hormonally active. These patients often have higher serum calcium levels and manifest more severe symptoms than those with hyperparathyroidism. Resection is the optimal therapy.

Neuroendocrine Tumors

Mediastinal NETs and carcinoid tumors arise from Kulchitsky cells located in the thymus and commonly occur in males in their 40s and 50s. They are usually located in the anterosuperior mediastinum. These tumors are aggressive and can spread to mediastinal and cervical lymph nodes, liver, bone, skin, and lungs. More than 50% of thymic NETs are hormonally active, often associated with Cushing syndrome due to production of adrenocorticotropic hormone. If feasible, resection is recommended; however, local invasion and metastasis often preclude complete excision. Radiation therapy is typically added for positive margins or gross residual disease after surgical resection. Systemic therapy is indicated for patients with unresectable recurrent or metastatic tumors.

ACKNOWLEDGMENT

We would like to thank Drs. Wald, Izhar, and Sugarbaker for their presentation of this chapter in the previous edition (20th edition), as we have updated their outstanding work.

> *In this pilot study, two preoperative doses of PD-1 inhibitor nivolumab were administered in adults with untreated, surgically resectable early (stage I, II, or IIIA) NSCLC. Nivolumab (at a dose of 3 mg per kilogram of body weight) was administered intravenously every 2 weeks, with surgery planned approximately 4 weeks after the first dose. Neoadjuvant nivolumab was associated with few side effects, did not delay surgery, and induced a major pathologic response in 45% of resected tumors. The tumor mutational burden was predictive of the pathologic response to PD-1 blockade. Treatment induced expansion of mutation-associated, neoantigen-specific T-cell clones in peripheral blood.*

National Lung Screening Trial Research Team, Aberle DR, Adams AM, et al. Reduced lung-cancer mortality with low-dose computed tomographic screening. *N Engl J Med*. 2011;365(5):395-409.

> *In this study, 53,454 patients from 33 medical centers at high risk for lung cancer were randomly assigned to undergo three annual screenings with either low-dose CT or single-view posterioranterior chest radiography. Over the 7-year period of the study, rates of adherence to screening were 90%. The study found that screening with low-dose CT reduces mortality from lung cancer.*

Pastorino U, Buyse M, Friedel G, et al. Long-term results of lung metastasectomy: prognostic analyses based on 5206 cases. *J Thorac Cardiovasc Surg*. 1997;113(1):37-49.

> *This is a registry of lung resections that has accrued 5206 cases of lung metastasectomy from 18 departments of thoracic surgery in Europe (n = 13), the United States (n = 4), and Canada (n = 1). Of these patients, 4572 (88%) underwent complete surgical resection. These results confirm that lung metastasectomy is a safe and potentially curative procedure. Resectability, disease-free interval, and number of metastases enabled the authors to design a simple system of classification valid for different tumor types.*

Importance of Performance Measures and Database Participation in Coronary Revascularization

INTRODUCTION

Cardiovascular disease is the leading cause of mortality globally, with an estimated 18 million deaths per year worldwide.[1,2] Of these deaths, 85% are due to myocardial infarction (MI) and stroke. Coronary artery disease (CAD), also known as *ischemic heart disease* (IHD), may present with angina pectoris, acute MI, or ischemic heart failure. According to the World Health Organization (WHO), 16.2% of all cardiovascular deaths globally stem from IHD, followed by stroke (10.8%), hypertensive heart disease (6.5%), cardiomyopathy (2.3%), rheumatic heart disease (RHD) (0.5%), atrial fibrillation (AF) (0.4%), aortic aneurysm (0.3%), peripheral arterial disease (PAD) (0.3%), endocarditis (0.2%), and venous thromboembolism (VTE) (0.1%).[1,2]

In the United States, CAD ranks as the number one cause of mortality, with 43.8% of all deaths attributable to cardiovascular diseases (Fig. 111.1).[3] This accounts for more than 365,914 deaths annually in the United States, followed closely by deaths from stroke and heart failure.[1,2] It is estimated that by 2035, more than 130 million adults in the United States (approximately 45.1% of the population) will have some form of CVD, and the total financial burden of CVD is expected to reach $1.1 trillion in 2035, with direct and indirect medical costs projected at $748.7 billion and $368 billion, respectively.[1–3]

CORONARY ARTERY ANATOMY AND PHYSIOLOGY

Basic understanding of cardiac pathophysiology is important to the general surgeon, who will often evaluate and operate on patients with CAD and other cardiovascular comorbidities.[4–6] For the cardiothoracic surgeon, in-depth knowledge of the complex anatomy of the coronary arteries and their variants and anomalies is critical. This in-depth understanding is critical in accurate diagnosis, appropriate management, and the prevention of procedural complications, ultimately improving patient outcomes.[4–6] In this section, an overview is provided of coronary circulation, important anatomic considerations, coronary perfusion, and the current understanding of CAD.

The major coronary arteries run from the top to the bottom of the interatrial and interventricular septa and encircle the atrioventricular grooves. Two coronary arteries—left and right—are the principal blood supply to the heart and are the first arterial branches of the aorta, each originating from its respective sinus of Valsalva.[5–7] The left coronary artery (LCA), also known as the *left main coronary artery* (LMCA), originates from the left coronary sinus and courses between the body of the left atrium and the main pulmonary artery, whereas the right coronary artery (RCA) arises from the right coronary sinus and runs rightward and obliquely in the right atrioventricular sulcus. The LCA varies in length from a few millimeters to several centimeters. It courses posterolateral to the main pulmonary trunk for about 1 cm before branching into the left anterior descending (LAD) and left circumflex arteries.[5–7] The LAD takes an anterolateral course relative to the pulmonary trunk and runs along the interventricular septum, supplying the left ventricular free wall and septum. Often, an arterial anastomosis between the LAD is formed at the apex of the heart with the posterior descending artery (PDA), a common branch of the RCA. The circumflex artery also travels along the atrioventricular groove and branches into marginal branches that travel toward the apex of the heart before terminating as the left posterolateral branch.[5–7]

The RCA provides the principal blood supply to the free wall of the right ventricle (RV) and, to a lesser extent, a part of the left ventricular circulation. Originating from the right coronary sinus, its ostium averages 2 to 3 mm in diameter.[5–7] It typically runs obliquely toward the right in the anterior atrioventricular sulcus. The RCA usually bifurcates into two pivotal branches—the PDA and right posterolateral artery. The PDA, often referred to as the *inferior interventricular artery,* supplies a critical portion of the blood supply for the inferior ventricular septum and adjacent ventricular walls. Its importance is underscored in individuals with right ventricular dominance, where the PDA, along with its septal perforating branches, significantly contributes to the blood supply of the septal papillary muscle of the mitral valve.[4–7] Other noteworthy branches of the RCA include the acute marginal artery (AMA), a consistent vessel that traverses the acute margin of the heart, reaching toward the apex. This branch is primarily responsible for supplying the lateral aspect of the RV. The AMA contributes to the formation of anastomoses at the apex of the heart, particularly with the anterior interventricular artery, a branch of the LCA. The atrio-ventricular node artery (AVNA) is another critical branch of the RCA, mainly because of its pivotal role in the cardiac conduction system. Originating from the RCA in most individuals, AVNA descends to supply the atrioventricular node, a critical component in the regulation of cardiac rhythm. This artery's course and branching pattern hold significant clinical importance because any compromise in its blood supply can lead to arrhythmias or heart block.[4–7]

Anatomic Considerations

Although the PDA arises from the RCA in up to 85% of humans (termed *right-dominant circulation*), there are other variants, including the so-called codominant circulation, in which the PDA arises from both the LCA and RCA. Codominant circulation accounts for approximately 7% of the population.[4–7] Left-dominant circulation is prevalent in 8% of patients, in which the PDA arises from the LCA. A retrospective analysis of 27,289 patients who presented for cardiac catheterization after a diagnosis of acute coronary syndrome (ACS) demonstrated that left-dominance circulation was associated with a mortality hazard ratio (HR) of 1.13

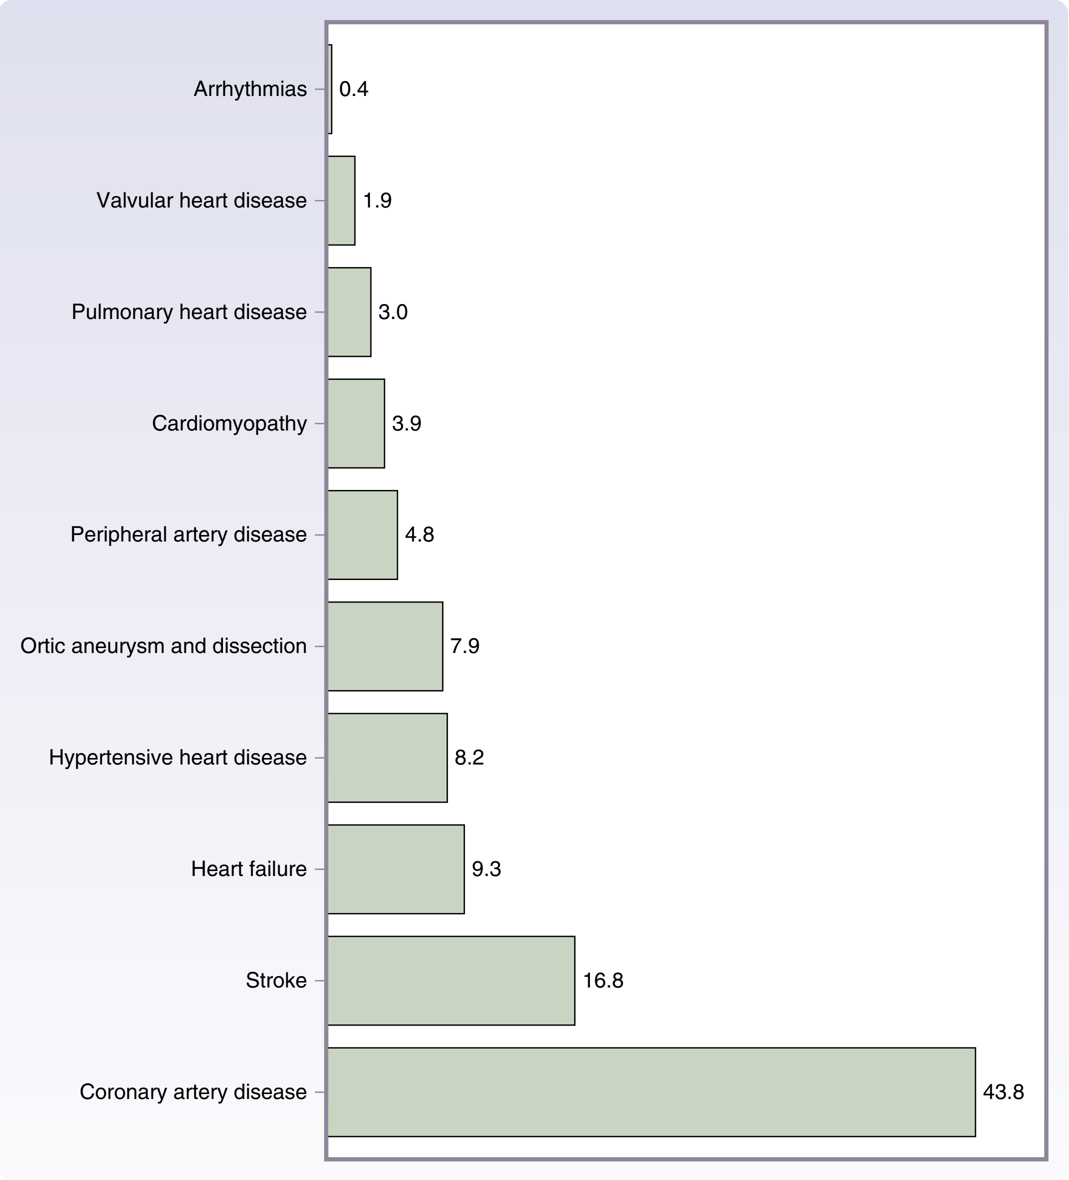

FIGURE 111.1 Top 10 causes of cardiovascular deaths in the United States. This bar graph presents the leading causes of cardiovascular deaths in the United States, based on CDC data. The *y*-axis lists the different cardiovascular conditions, and the *x*-axis represents the percentage of total cardiovascular deaths attributed to each condition. From lowest to highest, the conditions listed are arrhythmias, valvular heart disease, pulmonary heart disease, cardiomyopathy, peripheral artery disease, aortic aneurysm and dissection, hypertensive heart disease, heart failure, stroke, and coronary artery disease. Each bar's length indicates the proportion of cardiovascular-related deaths associated with each condition. *CAD,* Coronary artery disease; *CDC,* Centers for Disease Control and Prevention. (95% CI 1.00–1.28).[8] Codominance had the same mortality rate as right dominance.[8] More pronounced myocardial damage is theoretically possible in patients with either left or codominant circulation in scenarios involving lesions in the left circumflex and left main arteries because these branches would be responsible for supplying the PDA.[4–7] Given that 75% to 100% of the left ventricle is supplied by branches of the LMCA, significant left main (LM) stenosis is associated with an extraordinarily high risk of death.[9] Typically, patients with LM stenosis commonly have multivessel disease, with isolated LM coronary stenosis occurring in only 4% to 6% of cases.[9–11]

Physiology of Normal Coronary Perfusion

The cardiac subendocardium is particularly susceptible to ischemia.[12,13] A likely explanation for this stems from the observation that myocardial contraction itself impedes coronary blood flow to this innermost layer of the myocardium. Coronary vascular volume comprises a complex interplay of large and small arteries, capillaries, and small and large veins. In mild coronary artery stenosis, the heart may compensate appropriately using inherent autoregulatory vasodilatory processes.[12–14] To the extent that anatomic factors influence the delivery of oxygen to the heart, the very perfusion of the myocardium itself influences its function. Many studies have demonstrated that the filling of coronary vascular bed correlates with cardiac function, such that an increase in perfusion pressure increases myocardial oxygen consumption.[12–15] The nervous system also has a modulating function in cardiac perfusion in what is often described as a feed-forward mechanism. When stimulated by the nervous system, for example, coronary vessels often spontaneously vasodilate in synchrony with an increase in heart rate, and often before the arrival of the metabolic feedback at the resistance vessels.[8,13–15] In a healthy heart, coronary blood flow adjusts to the metabolic demands of the heart and can increase by a factor of 3 to 4. In the presence of coronary vascular disease, the resistance vessels initially undergo compensatory dilation, reducing the autoregulatory resistance per affected segment until it becomes zero. Once exhausted, the myocardial flow in the diseased segment can no longer be augmented by coronary autoregulation.[12–15]

Pathophysiology of Coronary Artery Disease

CAD is a complex, multifactorial disease characterized by the accumulation of atherosclerotic plaque in the coronary arteries, leading to myocardial ischemia and potentially fatal events such as MI. The pathogenesis of CAD is influenced by a variety of factors, including endothelial dysfunction, inflammation, and plaque formation.[6,16,17] Key components of the pathogenesis of CAD are outlined next.

Endothelial Dysfunction and Nitric Oxide Imbalance

The endothelium plays a pivotal role in maintaining vascular homeostasis. Endothelial cells produce nitric oxide (NO), a vasodilator that is vital for normal vascular tone. In CAD, risk factors like hypertension, hyperlipidemia, and tobacco use lead to endothelial dysfunction, characterized by reduced bioavailable NO and an imbalance between vasodilatory and vasoconstrictive regulation. This dysfunction marks the initial step in the atherogenic process, promoting an inflammatory environment within the vessel wall (Fig. 111.2), and contributes to vasoconstriction and plaque instability.[6,16,17]

Inflammation: T-Cell Activation and Recruitment of Proinflammatory Cytokines

The inflammatory process in CAD involves the recruitment of monocytes and T lymphocytes to the endothelium. Monocytes differentiate into macrophages, which ingest oxidized low-density lipoproteins (LDLs), transforming them into foam cells and contributing to plaque formation.[16,17] T cells, once activated, produce a range of cytokines, such as tumor necrosis factor-α (TNF-α) and interleukin (IL)-6, that further perpetuate the inflammatory response.[16,17] These proinflammatory cytokines also contribute to plaque instability by weakening the fibrous cap and promoting the secretion of matrix metalloproteinases (MMPs), enzymes that degrade the extracellular matrix. Plaque rupture, a major cause of ACSs, is often preceded by increased inflammatory activity within the plaque.[17]

Leukocyte Recruitment

In the early stages of atherosclerosis, endothelial cells, under the influence of risk factors such as hyperlipidemia and hypertension, express adhesion molecules and release chemokines like monocyte chemoattractant protein-1 (MCP-1). These molecules facilitate the adhesion of monocytes to the endothelium and their subsequent transmigration into the intima, the innermost layer of the artery.[16,17]

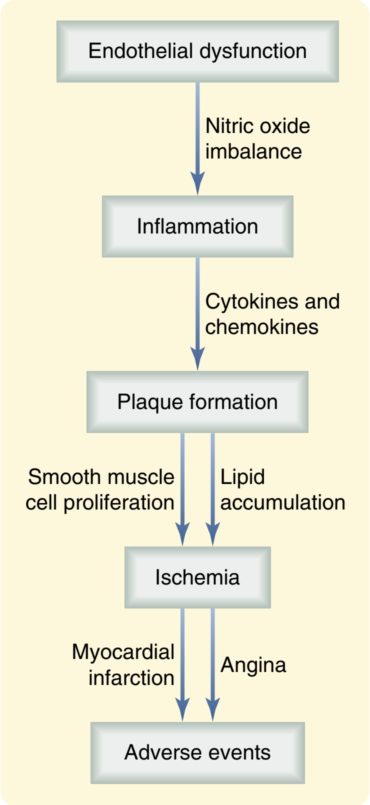

FIGURE 111.2 Proposed pathophysiology of CAD. Endothelial dysfunction plays a cardinal role and occurs early in the process, paving the path for a complex series of inflammatory reactions with subsequent plaque formation, coronary arterial stenosis, myocardial ischemia, and other clinical adverse effects, including myocardial infarction. *CABG,* Coronary artery bypass graft; *CAD,* coronary artery disease; *IHD,* ischemic heart disease; *SIHD,* stable ischemic heart disease. Plaque Formation and Mechanism of Acute Coronary Syndromes

The formation of atherosclerotic plaque represents a pivotal pathologic mechanism underpinning the evolution of CAD. This process is precipitated by endothelial dysfunction, attributable to an array of risk factors, including hyperlipidemia, arterial hypertension, diabetes mellitus, and tobacco use. Such dysfunction engenders increased arterial wall permeability, facilitating the transendothelial migration of LDLs.[5,16–18] Within the intimal layer, LDLs undergo oxidative modification to form oxidized LDL (oxLDL), which initiates an inflammatory cascade via the recruitment of inflammatory cytokines and chemokines, leading to monocyte adherence and infiltration into the intimal space. Subsequent differentiation of monocytes into macrophages and their assimilation of oxLDL via scavenger receptors culminates in foam cell formation. This event is augmented by the upregulation of endothelial adhesion molecules, namely, vascular cell adhesion molecule 1 (VCAM-1) and intercellular adhesion molecule 1 (ICAM-1), which facilitate the transendothelial migration of monocytes. The resultant accumulation of foam cells constitutes the initial visible pathology of atherosclerosis, known as *fatty streaks.*

Progression of CAD is further characterized by the migration of smooth muscle cells from the medial to the intimal layer, driven by cytokines and growth factors. These cells then synthesize extracellular matrix components, including collagen and proteoglycans, leading to the development of a fibrous cap overlaying the lipid-rich necrotic core, thus forming the mature atherosclerotic plaque. The integrity of this plaque is critical; its rupture or erosion precipitates thrombus formation, serving as a primary etiologic factor for ACSs such as MI and unstable angina (USA).[16–18]

The stability of atherosclerotic plaques is contingent on a delicate equilibrium between the synthesis and catabolism of extracellular matrix components. MMPs, synthesized by both macrophages and smooth muscle cells within the plaque, are instrumental in the degradation of the fibrous cap, thereby augmenting its susceptibility to rupture. Additionally, proinflammatory cytokines, such as IL-1β and TNF-α, exacerbate plaque vulnerability through the promotion of MMP expression, enhancement of inflammatory cell recruitment, and induction of apoptosis in smooth muscle cells. Understanding these molecular and cellular mechanisms is imperative for the development of targeted therapies and surgical interventions in the management of CAD.[5,16,17]

There are three primary processes by which atherosclerotic plaques can precipitate ACSs[18,19]:

1. Plaque Rupture: This occurs when the protective fibrous layer covering the plaque's fatty core breaks. This rupture allows blood to come into contact with the plaque's contents, leading to clot formation and potential vessel occlusion.
2. Plaque Erosion: This process involves the wearing away of the plaque's outer endothelial layer without the actual rupture of the plaque. As a result, blood is exposed to substances within the plaque that promote clotting, leading to thrombus development along the artery wall.
3. Calcified Nodule: In this case, hard, calcified deposits within the plaque break through the fibrous cap, potentially causing sudden occlusion of the artery if the nodules extend into the lumen.

The mechanisms leading to MI, specifically through the processes of plaque rupture, plaque erosion, and calcified nodules, significantly influence whether a patient experiences an ST-segment elevation myocardial infarction (STEMI) or a non–ST-segment elevation MI (NSTEMI). STEMI typically results from transmural occlusion of a coronary artery, often due to plaque rupture, leading to extensive myocardial damage. On the other hand, NSTEMI generally arises from partial occlusion or severe reduction of blood flow, not necessarily involving full thickness of the myocardium, and may be a result of plaque erosion or less significant plaque rupture.[5,18,19]

CLASSIFICATION OF ACUTE MYOCARDIAL INFARCTION (FOURTH UNIVERSAL DEFINITION)

MI, commonly known as a *heart attack,* is a major cardiovascular event that is classified into different types based on its etiology, clinical presentation, and underlying pathophysiology. The classifications are essential for guiding treatment strategies and predicting patient prognosis. The most recent and widely accepted classification is outlined in the Fourth Universal Definition of Myocardial Infarction, which categorizes MI into five main types.[18]

Type 1 Myocardial Infarction (Spontaneous Myocardial Infarction)

Type 1 MI is caused by a primary coronary event, such as atherosclerotic plaque rupture, erosion, or fissuring, leading to thrombus formation and subsequent myocardial ischemia and necrosis due to a decrease in coronary blood flow.[18,19]

Type 2 Myocardial Infarction (Ischemic Imbalance)

Type 2 MI occurs when there is an imbalance between the myocardial oxygen supply and demand not directly related to acute coronary thrombosis. Conditions such as coronary artery spasm, coronary embolism, anemia, arrhythmias, hypertension, or hypotension can precipitate this type of MI.[18]

Type 3 Myocardial Infarction (Sudden Cardiac Death)

Patients who die suddenly with symptoms suggestive of myocardial ischemia, accompanied by presumed new ischemic ECG changes, but for whom blood samples could not be obtained or were obtained too late after the onset of the ischemic event to allow for the documentation of elevated cardiac biomarkers, are classified as having had a type 3 MI.[18]

Type 4 Myocardial Infarction (Percutaneous Coronary Intervention–Related)

For type 4 MI, two subvariants have been identified: 4a and 4b. Type 4a MI is associated with percutaneous coronary intervention (PCI). It is defined by elevation in cardiac biomarkers (usually cardiac troponin) above the 99th percentile upper reference limit within 48 hours post-PCI.[20,21] Type 4b MI is related to stent thrombosis as documented by angiography or at autopsy.[18]

Type 5 Myocardial Infarction (Coronary Artery Bypass Graft–Associated)

Type 5 MI occurs after coronary artery bypass grafting (CABG) and is characterized by an increase in cardiac biomarkers (cardiac troponin) above the 99th percentile upper reference limit within 48 hours of CABG.[18]

CLINICAL MANIFESTATION AND DIAGNOSIS OF CORONARY ARTERY DISEASE

CAD may manifest as stable ischemic heart disease (SIHD) or ACS. Stable angina is often characterized by discomfort or a sensation of pressure beneath the sternum, which commonly intensifies during periods of physical exertion or emotional stress. This type of angina is distinguished by its predictable nature and chronic course, typically manifesting over a span of at least 2 months. The symptoms, which include chest pain or a feeling of tightening/squeezing, are usually alleviated upon resting or with the administration of nitroglycerin.[15,17,18,22] The pattern of pain onset during activity and its resolution during rest or through medication is a hallmark of this condition, distinguishing it from other forms of cardiac and noncardiac chest pain. Despite the fact that angina is the typical symptom of CAD, it is important to note that females are more likely to have atypical presentation and symptoms of CAD, including fatigue, indigestion, abdominal pain, nausea, and vomiting, compared with males (see later discussion).

The clinical presentation of ACS is typically marked by substernal chest discomfort, often described as pressure or tightness, which may radiate to the neck, jaw, or left arm. USA is present when previously noted symptoms become more frequent or have increased intensity. This symptomatology is frequently precipitated by plaque rupture and subsequent thrombosis within the coronary arteries, leading to a critical reduction in blood flow to the myocardium.[15,17,18,23] Patients with ACS may exhibit a constellation of associated symptoms, reflecting the severity of myocardial ischemia and the body's response to the acute cardiac event. Dyspnea is a common finding, likely resulting from the interplay of increased cardiac workload and the potential for subsequent pulmonary congestion due to left ventricular dysfunction. Palpitations and dizziness may occur, reflecting arrhythmogenic potential or hemodynamic instability associated with the acute ischemic event. Syncope, a concerning symptom, may signal significant arrhythmias or profound myocardial dysfunction.[15,17,18,22]

In certain cases, ACS may precipitate cardiac arrest, denoting a critical and life-threatening manifestation of the syndrome, necessitating immediate resuscitative efforts. Moreover, new-onset congestive heart failure may manifest in the setting of ACS, indicating substantial myocardial injury and compromised cardiac output, necessitating aggressive medical management and careful hemodynamic monitoring. It is crucial to note that the relief of symptoms with nitroglycerin should not be misconstrued as a diagnostic criterion for myocardial ischemia, given that other pathophysiologic entities, such as esophageal spasm, exhibit a similar therapeutic response.[15,18]

PHYSICAL EXAMINATION IN PATIENTS WITH CORONARY ARTERY DISEASE

A thorough history and physical examination are important in the diagnosis of CAD and in the consideration of a patient for surgical revascularization. This is especially the case given the diagnostic challenges in delineating other life-threatening and benign causes of angina. For example, ACS may present with diaphoresis, tachypnea, and tachycardia, but pulmonary embolism may have similar features. Furthermore, aortic dissection may manifest with severe chest or back pain and limb pulse differentials, abdominal pain, or stroke symptoms. Noncoronary causes like aortic stenosis and pericarditis have their own characteristic symptoms and murmurs. Therefore, it is important to formulate a clinical suspicion rapidly and integrate other helpful diagnostic tools to correctly identify the underlying cause of chest pain.[17,18,22,24]

Physical exam during the initial encounter of a patient with CAD should include inspection, palpation, and auscultation. Inspection should methodically assess for signs of hemodynamic compromise, such as jugular venous distention (JVD), indicative of elevated central venous pressure potentially due to heart failure or volume overload. Peripheral edema, another critical sign, warrants careful evaluation for its extent and severity because it may reflect systemic venous congestion, often seen in right heart failure or systemic conditions affecting the venous return. During palpation, the surgeon should discern the presence of a fluid thrill, suggestive of significant pericardial effusion, or a precordial heave, indicative of ventricular hypertrophy or profound ventricular dilation. The grading of peripheral edema is essential for quantifying the degree of fluid retention and guiding therapeutic interventions.[17,18,23,24] Auscultation of the carotid arteries may reveal transmitted valvular murmur or carotid stenosis. Auscultation of the lungs may reveal pulmonary congestion of congestive heart failure, and auscultation of the precordium may be diagnostic of primary or contributing valvular stenosis or regurgitation.

DIAGNOSTIC TESTING IN PATIENTS WITH CORONARY ARTERY DISEASE AND BEFORE SURGICAL REVASCULARIZATION

Electrocardiogram

Patients with chest pain and new ST elevation, ST depression, or a new left bundle branch block on ECG should be treated according to STEMI and non–ST-segment elevation acute coronary syndrome (NSTE-ACS) guidelines. An initial normal ECG does not exclude ACS. Patients with an initial normal ECG should have a repeat ECG if symptoms are ongoing, until other diagnostic testing rules out ACS. An ECG may identify other nonischemic causes of chest pain (e.g., pericarditis, myocarditis, arrhythmia).[20–22,24]

When an ECG is nondiagnostic, it should be compared with previous ECGs, if available. A normal or unchanged ECG is reasonably useful but not sufficient in ruling out ACS because up to 6% of patients with evolving ACS are, unfortunately, discharged from the emergency department (ED) with a normal ECG.[5,22] In patients where the initial ECG is normal or is without ST elevation, serial ECGs should be performed, and management should be guided by new electrocardiographic changes or other diagnostic testing. The timing for repeat ECG should also be guided by symptoms, especially if chest pain recurs or a change in clinical condition develops.

Chest Radiograph

Obtaining a chest radiograph (CXR) is recommended to assess the size of the heart and identify pulmonary congestion and other potential intrathoracic causes of chest discomfort. CXR may demonstrate a widened mediastinum in patients with aortic dissection. Relative to CAD and in preparation for potential CABG, CXR allows one to assess for pulmonary edema and the presence of acute pneumonia, aortic calcification, lung masses, and enlarged aortic silhouette, which may necessitate further evaluation to define the optimal surgical strategy and help anticipate potential complications.[24]

Cardiovascular Biomarkers

The preferred biomarker to detect or exclude myocardial injury is troponin (cTn I or T) because of its high sensitivity and specificity for myocardial tissue. The addition of creatine kinase MB (CK-MB) or myoglobin to cTn for the evaluation of patients with ACS has not been shown to be beneficial.[24] Biomarker cutoffs for the diagnosis of MI differ between institutions and in clinical trials and are usually represented in reference to an upper reference limit for the specific biomarker.

Transthoracic Echocardiography

Transthoracic echocardiography (TTE) is the first-line imaging modality for the evaluation of left ventricle (LV) and RV systolic and diastolic function. It provides essential information about the LV and RV ejection fraction, wall motion abnormalities, and other indices of systolic function. In the context of ACS, TTE can identify regional wall motion abnormalities indicative of ischemia or infarction.[24,25] TTE is also crucial for the assessment of valvular structure and function. It can identify valvular stenosis or regurgitation, vegetations in the case of endocarditis, and other structural abnormalities that may contribute to or mimic the clinical presentation of ACS. If the presentation of MI is late in the course, TTE can also identify post-MI mechanical complications, such as ventricular septal defect (VSD), papillary muscle rupture (PMR), and severe mitral regurgitation, or free-wall rupture. Finally, preoperative TTE may help provide insight into the potential need for concomitant cardiac procedures in patients undergoing surgical coronary revascularization.[24,25]

Fractional Flow Reserve, Instantaneous Wave-Free Ratio, Optical Coherence Tomography, and Intravascular Ultrasound

Fractional flow reserve (FFR) is an important tool in determining whether coronary atherosclerotic plaques are physiologically responsible for myocardial ischemia, guiding the need for revascularization.[26–30] The procedure involves the insertion of a guidewire equipped with a pressure sensor distal to the coronary stenosis. After the administration of a vasodilator to induce hyperemia, FFR is calculated as the ratio (0 to 1.00) of the mean distal coronary pressure (measured by the pressure sensor on the guidewire) to the mean aortic pressure (measured by the coronary catheter). The FFR value reflects the maximum achievable blood flow in the presence of a stenosis compared with the hypothetical maximum flow in the absence of the stenosis. A lower FFR value indicates a more significant blockage, whereas a higher FFR value suggests less severe narrowing. The commonly accepted threshold for FFR interpretation is 0.80. An FFR value of 0.80 or lower suggests that the coronary artery blockage is hemodynamically significant, meaning it is likely causing reduced blood flow to the myocardium.[26–30] FFR-guided PCI has shown superiority over angiography-guided PCI and medical therapy alone.[26–32] It remains the gold standard for detecting ischemia-inducing coronary stenoses and is still unsurpassed in diagnostic performance compared with nonhyperemic indices and noninvasive techniques. The FAME (Fractional Flow Reserve Versus Angiography for Multivessel Evaluation) trial[26] consisted of patients with multivessel CAD randomized to receive stents based on angiographic appearance only versus when FFR was ≤ 0.80. The 2-year follow-up study found that FFR-guided PCI was associated with fewer number of total stents used (1.9 ± 1.3 vs. 2.7 ± 1.2, respectively; $p < 0.001$) and lower rates of MI or death within 2 years (8.4 vs. 12.9%, $p = 0.02$) compared with patients with angiography-only–guided revascularization.[26]

The **instantaneous wave-free ratio (iFR)** employs high-frequency sampling to compute a pressure gradient across a coronary lesion during diastole, and its performance has been evaluated in comparison to FFR.[31,33] It has the added advantage of minimizing the use of hyperemic agents like adenosine, which can be uncomfortable for patients. Multiple clinical trials have investigated the value of iFR in assessing CAD severity. Specifically, the DEFINE-FLAIR (Functional Lesion Assessment of Intermediate Stenosis to Guide Revascularization) trial[34] demonstrated that iFR is noninferior to FFR in guiding revascularization decisions. Notably, in patients with angina or anginal-equivalent symptoms, undocumented ischemia, and angiographically intermediate stenoses, the use of FFR or iFR to guide the clinical decision for PCI carries a Class 1, Level A evidence-based recommendation.[21] FFR-guided PCI or CABG in the FAME 3 trial demonstrated no difference at 3 years in the composite incidence of death, MI, or stroke; however, there was a higher incidence of MI after PCI versus CABG.[33] It remains unclear if FFR provides additional information in CABG planning to that provided by routine diagnostic angiography.

Optical coherence tomography (OCT) is an advanced imaging technique that is used to estimate the severity of CAD by examining the microstructure of coronary arteries before revascularization. As a diagnostic tool, OCT proves useful in patients with borderline lesions found on angiography because of its high spatial resolution.[35] The 2021 American College of Cardiology (ACC)/American Heart Association (AHA)/Society for Cardiovascular Angiography and Interventions (SCAI) Guideline for Coronary Artery Revascularization currently has a Class 2a recommendation for the use of OCT to guide stent placement as an alternative to intravenous ultrasonography (IVUS) except in patients with ostial left main disease.[21] Post-PCI, OCT has also been found to be beneficial in assessing complications such as stent underdeployment and malposition. Furthermore, OCT has become essential in diagnosing MI with nonobstructive coronary arteries. By detecting PCI complications that might otherwise be missed by angiography, OCT remains an important tool in coronary revascularization.[35]

IVUS, a catheter-based imaging modality, complements angiography by providing valuable diagnostic information, including vessel and lumen dimensions, plaque burden, and morphology, particularly in patients with LMCA stenosis.[36,37] In a recent systematic review and meta-analysis comparing IVUS-guided versus coronary angiography–guided PCI in patients with acute MI (AMI), IVUS-guided PCI was associated with a significantly lower risk of all-cause mortality, reduced major adverse cardiac events (MACEs), and target vessel revascularization (TVR). Notably, among patients with STEMI, the use of IVUS-guided PCI was linked to a lower likelihood of all-cause mortality (relative risk [RR] 0.79, 95% CI 0.66–0.95, $p = 0.01$) and MACEs (RR 0.86, 95% CI 0.74–0.99, $p = 0.04$).[36] Currently, the use of IVUS to define lesion severity in patients with intermediate stenosis of the left main artery constitutes a Class 2a recommendation by the ACC/AHA/SCAI Guideline for Coronary Artery Revascularization.[21]

Coronary Computed Tomography Scan

CT, particularly coronary CT angiography (CCTA), has emerged as a valuable tool for the noninvasive assessment of CAD. It provides detailed images of the coronary anatomy, allowing for the visualization of coronary artery stenosis, plaque characteristics, and the extent of aortic calcification, which is a marker of atherosclerotic burden.[38–45] Like conventional chest CT scan, CCTA is noninvasive and can now be performed with low radiation doses and high diagnostic accuracy. Because its high negative predictive value (NPV) for CAD, CCTCA has become important for the assessment of patients with recent-onset chest pain. Multiple clinical trials (International Study of Comparative Health Effectiveness with Medical and Invasive Approaches [ISCHEMIA], Scottish Computed Tomography of the HEART [SCOT-HEART], and Prospective Multicenter Imaging Study for Evaluation of Chest Pain [PROMISE]) suggest that combining coronary anatomy and functional assessment of coronary flow with myocardial tissue characterization by CT can provide a comprehensive evaluation of CAD.[41,44] Given its noninvasive nature and relative ease of performance, it is an important adjunct in anatomic plaque characterization and evaluation of the severity of calcification. It is also diagnostic in the presence of anomalous coronary anatomy. Positron emission topography (PET) with newly adopted radiotracers and CCTA assessments, such as pericoronary adipose tissue density (PCAT), are gaining attention for their potential to improve cardiac risk prediction.[38–40,45]

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA), another noninvasive imaging technique with high spatial and temporal resolution, provides detailed anatomic and functional cardiac assessment. Cardiac MRA allows for accurate and reproducible measurement of left ventricular ejection fraction (LVEF) without the geometric assumptions required by other imaging techniques, making it the gold standard for volumetric assessment. In addition to LVEF, cardiac MRA can assess ventricular volumes, mass, and myocardial viability, offering a holistic view of cardiac function.[46–49]

For valvular function assessment, cardiac MRA provides a noninvasive means to evaluate valvular morphology, leaflet motion, and the extent of valvular regurgitation or stenosis. The technique's ability to visualize blood flow using phase-contrast imaging enables precise quantification of flow across valves, aiding in the diagnosis and management of valvular heart diseases.[48–50]

MRA offers several advantages over traditional angiography, such as the absence of ionizing radiation, the potential for noncontrast examination, high spatial resolution, superior soft tissue differentiation, and lower cost.[44,48,49] There is a growing emphasis on using more noninvasive methods like MR angiography for initial diagnosis, reserving the cardiac catheterization lab for interventional procedures once a diagnosis is established. A large systematic review and meta-analysis examined the diagnostic performance of MR coronary angiography (MRCA) for CAD.[48,49] The meta-analysis, involving 24 studies with 1638 patients, revealed that the pooled sensitivity of MRCA for CAD was 89%, with a specificity of 72%. Interestingly, the use of contrast-enhanced examinations increased the sensitivity to 95%, comparable to that of CTA. The specificity was higher in whole-heart acquisition mode (78%) compared with targeted mode (57%), and it was also higher at 3-Tesla (T) magnetic field strength (83%) compared with 1.5 T (68%). These results indicate that whole-heart contrast-enhanced protocols at higher magnetic field strengths might offer the best approach for MRCA in CAD diagnosis.[48,49]

Stress Testing

Stress testing serves as a fundamental noninvasive method for evaluating individuals who may have or are known to have CAD and may include pharmacologic stress (dobutamine) test, exercise stress testing, stress echocardiography, nuclear stress (myocardial perfusion imaging) test, and stress cardiac magnetic resonance (CMR) imaging.[39,51] Stress testing is primarily used to determine a patient's risk stratification or to evaluate the need for coronary angiography. Although exercise stress testing does not typically involve contrast or radiation, nuclear stress testing does involve the use of a radioactive tracer and imaging. Individuals with stable CAD often fall into the low-risk category after stress testing and are spared a more invasive diagnostic workup, such as coronary angiography. Therefore, for patients who have a normal or nearly normal resting ECG and can exercise adequately, standard exercise treadmill testing is usually the first choice. However, for those with a history of revascularization, ECGs that are difficult to interpret, or those unable to perform sufficient exercise, stress imaging is advised.[52] Of note, among patients referred for treadmill stress test by their family medicine physicians, a series documented the average sensitivity as 71.4%, and the average specificity was 90.4%. Furthermore, this study reported a positive predictive value (PPV) of 13.5% and an NPV of 99.3%.[52]

Diagnostic Cardiac Catheterization

Coronary angiography is commonly used to evaluate and determine the structure, extent of narrowing (stenosis), and location of the coronary arteries. Cardiac catheterization involves the insertion of a catheter, typically 2 to 3 mm in diameter, into veins or arteries in the neck (internal jugular vein), arm (radial arteries [RAs]), and groin (femoral vessels) under local anesthesia. From there, the catheter is advanced to the right and/or left sides of the heart. Two main types exist: (1) left heart catheterization, primarily performed for diagnostic purposes, including the evaluation of CAD, and it may also include therapeutic interventions like angioplasty or stenting, and (2) right heart catheterization (pulmonary artery or Swan-Ganz catheterization), which provides direct measurement of pressures within the heart and pulmonary artery, blood sampling from these areas, and the calculation of cardiac output. For a more accurate assessment of coronary anatomy, it is important to acquire multiple angiographic angles. Furthermore, the addition of physiologic testing (as detailed earlier) may help provide a more thorough evaluation.

A stenosis is considered significant if it reduces coronary artery diameter by 70% or more in non–left main coronary arteries or by 50% or more in the LMCA.[21,53,54] Angiographic stenosis with a diameter reduction between 40% and 69% is considered intermediate and typically requires further testing to evaluate its physiologic impact. Notably, coronary angiography alone does not provide a standard measurement for the length of lesions, which is an important clinical factor for potential revascularization.[53,54] Controversy exists as to whether visual estimation or quantitative analysis of angiography is more effective in predicting the functional impact of a stenosis. The discrepancy in measurement between these two methods (visual or physiologic) can range from 10% to 20%, varying with the severity of stenosis.[54]

The access for cardiac catheterization is typically via the femoral or RA. Transradial cardiac catheterization has a Class 1 recommendation in the ACC/AHA/SCAI 2021 Guideline for Coronary Artery Revascularization over transfemoral approach in patients with ACS undergoing PCI to reduce the risk of death, vascular complications, or bleeding and in patients with SIHD undergoing PCI to reduce access site bleeding and vascular complications (Table 111.1).[21] It is important to recognize the potential complications associated with coronary catheterization, including vascular injuries (dissection, pseudoaneurysm [pSA], aneurysm, rupture, and occlusion) and others, including infection and contrast-related morbidities (up to 7.1% rate of kidney injury in the National Cardiovascular Data Registry).[55] The use of the RA for coronary catheterization may result in dissection or occlusion of the vessel and render it unacceptable for future harvest as an arterial conduit for CABG.[21,56–59]

Left Ventriculography

LV ventriculography, or LVgram, involves inserting a catheter into the LV, injecting contrast under fluoroscopy, and visually estimating the ejection fraction and degree of mitral regurgitation. It can also assist in diagnosis of post infarction VSD or pseudoaneurysm[60,61] and for visualizing calcification in the ascending aorta. This diagnostic tool is not used in patients with aortic endocarditis, aortic stenosis, or renal insufficiency (because of the amount of contrast required).

Aortic Gradient Evaluation

An evaluation of the pressure gradient across the aortic valve during cardiac catheterization may be performed to assess the degree of aortic stenosis. This is critical in patients being evaluated for CABG because significant aortic stenosis can affect both the decision to proceed with CABG at all and the need for concurrent aortic valve intervention during CABG.

Left Ventricular End-Diastolic Pressure

Evaluating the left ventricular end-diastolic pressure (LVEDP) during cardiac catheterization is helpful in patients with reduced

TABLE 111.1 **Indications for CABG in Patients With STEMI, NSTE-ACS, and SIHD**

	CLASS OF RECOMMENDATION		
PATIENT STATUS	**COR 1 (BENEFIT >>> RISK)**	**COR 2A (BENEFIT >> RISK)**	**COR 2B (BENEFIT ≥ RISK)**
STEMI			
	Patients with **STEMI** and cardiogenic shock or hemodynamic instability, CABG when PCI is not feasible is indicated **to improve survival**	Patients with **STEMI** when PCI not possible or successful, with a large area of myocardium at risk emergent or urgent CABG can be effective to **improve clinical outcomes**	
	Patients with **STEMI** with mechanical complications (ventricular septal rupture, mitral insufficiency due to papillary muscle infarction or rupture, or free wall rupture), CABG is recommended at the time of surgery **to improve survival**	Patients with **STEMI** with complex MV non-infarct CAD, after successful PCI, elective CABG is reasonable **to reduce the risk of cardiac events**	
NSTE-ACS			
	Patients with **NSTE-ACS** and cardiogenic shock who are appropriate candidates for revascularization, emergency revascularization is recommended **to reduce risk of death**	Patients with **NSTE-ACS** who are initially stabilized and are at intermediate or low risk of clinical events, an invasive strategy with intent to perform revascularization is reasonable before hospital discharge **to improve outcomes**	
		Patients with **NSTE-ACS** who have failed PCI and have ongoing ischemia, hemodynamic compromise, or threatened occlusion of an artery with substantial myocardium at risk, emergency CABG is reasonable	
SIHD			
LV dysfunction			
	Patients with **SIHD** and MV CAD appropriate for CABG with severe LV dysfunction (LVEF <35%), CABG is recommended **to improve survival**	Patients with **SIHD** and MV CAD appropriate for CABG with mild to moderate LV dysfunction (LVEF 35-50%), CABG (to include LIMA to LAD) is reasonable **to improve survival**	
Left Main CAD			
	Patients with **SIHD** and significant LM stenosis, CABG is recommended **to improve survival**		
MV CAD			
		Patients with **SIHD** and MV CAD, revascularization is reasonable **to lower the risk of cardiovascular events**	Patients with **SIHD**, normal LVEF, significant stenoses in 3 major coronary arteries, and anatomy suitable for CABG, CABG may be reasonable **to improve survival**
Refractory Angina			
	Patients with refractory angina despite medical therapy and with significant coronary artery stenoses amenable to revascularization, revascularization is recommended **to improve symptoms**

LVEF, especially in the context of CABG evaluation. Accurate measurement of LVEDP is achieved by placing a catheter into the LV to directly measure the pressure at the end of diastole. This measurement is particularly important in patients with symptoms of heart failure or those with suspected diastolic dysfunction. This information assists in risk stratification and can influence the surgical approach and the need for additional interventions or mechanical adjuncts during revascularization.[62]

Society of Thoracic Surgeons Risk Scoring

The Society of Thoracic Surgeons (STS) operative risk calculator is a tool designed to evaluate and predict the mortality and morbidity risk associated with various operative procedures in cardiac surgery. This calculator takes various factors into consideration, including the planned surgery; patient demographics (age, sex, race, body weight, and height); laboratory values (creatinine, hematocrit, white blood cell [WBC] and platelet count); preoperative medications, including inotropes ≤48 hours; and risk factors (diabetes, family history of CAD, liver disease, mediastinal radiation, endocarditis, alcohol and tobacco use; presence of chronic lung disease, prior stroke, New York Heart Association [NYHA] classification, valvular disease, and preoperative arrhythmia).[63] The STS score has been validated by several studies and has been demonstrated to perform better than the EuroSCORE II, especially in patients with higher STS predicted risk of operative mortality (PROM) (>5%).[64] Notably, patients with cirrhosis, frailty, and chronic malnutrition may benefit from additional risk estimation models. The outcomes predicted by the STS risk calculator include risk of mortality and risk of morbidity (renal failure, permanent stroke, prolonged ventilation, deep sternal wound infection, reoperation, and prolonged length of stay). The ACC/AHA/SCAI 2021 Guideline for Coronary Artery Revascularization gives a Class 1 recommendation supporting the calculation of the STS risk score at the time of CABG evaluation.[21] The calculator may be accessed at https://acsdriskcalc.research.sts.org/.

Synergy Between Percutaneous Coronary Intervention With TAXus and Cardiac Surgery Score

In determining the most suitable revascularization approach for patients with CAD, several factors should be considered: the complexity of the CAD, the likelihood of achieving complete revascularization (CR), the risk of adverse outcomes, patient preferences, patient symptoms, LVEF, potential for adherence to dual-antiplatelet therapy (DAPT), and more. To assist in making informed decisions, the Synergy Between Percutaneous Coronary Intervention With TAXus and Cardiac Surgery Score (SYNTAX) score was created based on the SYNTAX trial.[65–70] Initially introduced by Sianos et al. in 2005, the score serves as an angiographic tool for grading the complexity of CAD.[65]

Subsequent studies have explored its utility in various contexts. Wykrzykowska et al. (2010) and Garg et al. (2011) examined the score's prognostic implications for 1-year outcomes and risk stratification.[68,69] Généreux et al. (2011) scrutinized the score's reproducibility among healthcare providers,[66] and Zhang et al. (2014) proposed and expanded its application by incorporating site-specific scores and clinical factors for improved decision-making.[71] Cavalcante et al. (2017) extended its application to diabetic patients with multivessel CAD.[72] Moreover, Farooq et al. (2013) and Takahashi et al. (2020) worked on the development and validation of SYNTAX score II, which combines anatomic and clinical factors to guide decision-making between CABG and PCI.[68,73] Several studies have shown that a patient's SYNTAX score can be an important effect modifier that favors surgical revascularization versus PCI.[68,71,72]

Important limitations of the SYNTAX score are worth mentioning. First, the SYNTAX scoring system is cumbersome and is subject to interobserver variability.[66] Additionally, the SYNTAX score does not incorporate some important clinical variables, which limits its usefulness in comprehensively estimating the accurate risk of clinical events after CABG.[66,71] The ACC/AHA/SCAI 2021 Guideline for Coronary Artery Revascularization gives a Class 2b recommendation supporting the use of scoring models such as the SYNTAX score to guide revascularization in patients with multivessel CAD.[21]

HISTORY OF CORONARY ARTERY BYPASS SURGERY

Coronary artery revascularization has a storied history that reflects a journey marked by extensive research, clinical experimentation, and evolving surgical techniques. Key milestones (Fig. 111.3) include the Nobel Prize–winning work of Alexis Carrell in blood vessel anastomoses (1902, awarded prize in 1912), the development of the heart-lung machine (John Gibbon Jr., 1930s and 1940s), and the groundbreaking discovery of coronary arteriography by Frank Mason Sones in 1957. Notably, in 1929, Werner Forssmann performed the first cardiac catheterization on himself, establishing a foundation for future cardiac diagnostic and therapeutic techniques. Subsequently, in 1955, Denis Melrose revolutionized cardiac surgery by introducing potassium cardioplegic arrest. Building on these advancements, Gerald Buckberg elucidated the advantages of employing hypothermia to reduce myocardial oxygen consumption, alongside advocating for warm induction and warm cardioplegia after cardiac arrest. His work emphasized the superiority of blood cardioplegia over other methods, further refining cardiac surgery techniques and improving patient recovery and outcomes.[5,74] The 1960s marked significant advances with successful aortocoronary vein grafts, beginning with the first human aortocoronary bypass graft by David Sabiston Jr. (Fig. 111.4) and the identification of collateral formation in bypass surgeries. This era also recognized the multifactorial nature of atherosclerosis, shifting the focus from mere obstruction to cellular composition and inflammation in plaques. Large-scale studies underscored smoking and abnormal lipids as primary risk factors.

Notably, David Sabiston Jr. significantly contributed to the standardization of CABG through his relentless emphasis on evidence-based practices. His innovative surgical techniques and research in heart physiology and coronary circulation directly contributed to the optimization of CABG procedures and patient outcomes.[74,75] Furthermore, he profoundly influenced surgical education, notably through the *Sabiston Textbook of Surgery* and the *Sabiston and Spencer Surgery of the Chest,* both pivotal educational contributions to surgical training.[5,74]

Over the past 65 years, coronary artery surgery has seen dozens of major advancements, including minimally invasive techniques and improved myocardial protection, significantly reducing mortality rates. Today, the objectives of coronary artery surgery encompass not only symptom relief and improved left ventricular function but also the extension of life span and reduction of late cardiac events.

FIGURE 111.3 Key developments in the history of CABG. From preclinical experiments to small and large animal models, there have been tremendous advancements to optimize the safety and well-being of patients with CAD who undergo CABG. In the face of newer and exciting percutaneous coronary interventions, CABG continues to be important in patients with reduced left ventricular ejection fraction, diabetes, complex CAD, left main CAD, recurrent in-stent stenosis, and dual-antiplatelet therapy nonadherence. *CABG,* Coronary artery bypass graft; *CAD,* coronary artery disease; *CASS,* coronary artery surgery study; *ITA,* internal thoracic artery; *LAD,* left anterior descending; *LITA,* left internal thoracic artery; *MIDCAB,* minimally invasive direct coronary artery bypass; *VA,* Veterans Affairs Coronary Artery Bypass Surgery Cooperative Study. INDICATIONS FOR CORONARY ARTERY REVASCULARIZATION: ACUTE CORONARY SYNDROMES

The 2021 ACC/AHA/SCAI Guideline for Coronary Artery Revascularization offers evidence-based recommendations regarding the role of surgical revascularization versus PCI. Tables 111.1 and 111.2 and Fig. 111.5 summarize the indications and best practices for the treatment of patients with STEMI, NSTE-ACS, and SIHD.[21] ACS comprises a spectrum of clinical conditions resulting from acute myocardial ischemia due to a significant reduction or cessation of blood flow in a coronary artery or arteries. This spectrum encompasses STEMI; NSTEMI, now more broadly referred to as *NSTE-ACS;* and USA. The pathophysiology primarily involves atherosclerotic plaque disruption and subsequent thrombus formation, leading to partial or complete occlusion of the coronary artery.[15,17,18] STEMI is characterized by full-thickness myocardial damage and is identifiable by ST elevation on ECG. In contrast, NSTEMI, often resulting from partial occlusion, is diagnosed based on cardiac biomarkers without ST elevation on ECG. USA, meanwhile, presents as a change in anginal patterns (severity, frequency, changing from exertion to rest pain) without a detectable change in cardiac enzymes.[15,17,18]

The management of ACS is multifaceted, including rapid revascularization, pharmacotherapy, and lifestyle modifications, all of which are aimed at restoring coronary blood flow, reducing myocardial oxygen demand, and ultimately preventing further cardiac events.[21]

ST-Elevation Myocardial Infarction

In patients with STEMI with symptoms <12 hours, PCI should be performed to improve survival (Class 1).[14] Evidence from multiple randomized controlled trials (RCTs) and meta-analyses underscores the efficacy of primary PCI over fibrinolysis, significantly curtailing death, MI, stroke, and major bleeding, particularly with minimized treatment delays. Notably, this benefit extends to patients referred from non-PCI facilities, with the caveat of reasonable transfer times and total ischemic duration under 120 minutes.[21,76,77]

The role of CABG in the acute phase of STEMI is limited, and its application in this context has declined over time. Historical case series have indicated a potential increase in mortality risk when CABG is conducted shortly after STEMI. Nonetheless, recent advancements in operative techniques, enhanced anesthesia and monitoring, refined technical methods, and the use of adjunctive

TABLE 111.2 Clinical Scenarios When CABG Is Preferred Over PCI—cont'd

	CLASS OF RECOMMENDATION		
PATIENT STATUS	**COR 1 (BENEFIT >>> RISK)**	**COR 2A (BENEFIT >> RISK)**	**COR 2B (BENEFIT ≥ RISK)**
Previous CABG		Patients with **previous CABG** and **refractory angina** on GDMT that is attributable to LAD disease, it is reasonable to choose CABG over PCI when an IMA can be used to the LAD	Patients with **previous CABG** and **complex CAD**, it may be reasonable to choose CABG over PCI when an IMA can be used to the LAD
DAPT Adherence		Patients with **MV CAD** who are **unable to access, tolerate, or adhere to DAPT** for the appropriate duration of treatment, CABG is reasonable in preference to PCI	
In Stent Stenosis		Patients with **symptomatic recurrent diffuse ISR** with an indication for revascularization, CABG can be useful over repeat PCI **to reduce recurrent events**	

Note: CABG is preferred over PCI in patients with previous CABG presenting with complex CAD or refractory angina due to LAD disease when a LIMA may be used (COR 2a), in patients who are unable to adhere to DAPT therapy (COR 2a), and in patients with complex CAD and previous CABG (COR 2b) to improve survival. CABG is also preferred to PCI in patients with symptomatic recurrent ISR to reduce recurrent events (COR 2a). *Revascularization* refers to PCI or CABG.

temporary mechanical circulatory support devices may contribute to improved survival rates after CABG.[21,78] In STEMI patients with complex multivessel CAD, elective CABG stands as a viable revascularization choice after successful PCI of the culprit infarct artery, provided the patient is a CABG candidate. For those with complex noninfarct artery disease, deliberations regarding PCI or CABG for the noninfarct artery(s) should involve a collaborative heart team discussion.[21]

In most STEMI patients with multivessel disease and concurrent cardiogenic shock, a prompt PCI revascularization of the culprit vessel is the recommended strategy. This recommendation is founded on consistent observations from observational studies and one randomized trial, both indicating no benefit and potential harm from immediate multivessel PCI.[21] Complex disease, such as severe left main or multivessel CAD, may render PCI of the infarct artery impractical in STEMI patients. Furthermore, there are unique instances where PCI might not achieve the desired result. Under these scenarios, employing CABG as the initial strategy for restoring blood flow can be highly beneficial, especially when a substantial portion of the heart muscle is in jeopardy.[21]

Non–ST-Elevation Acute Coronary Syndrome

In patients with NSTE-ACS who are at an increased risk of further ischemic events, an invasive strategy may be employed with the intent to proceed with revascularization if appropriate (see Fig. 111.5).[21] In these patients, risk stratification using the Global Registry of Acute Coronary Events (GRACE) 2.0 risk calculator (score ≥140 is associated with increased risk for cardiac events) is crucial to guide the timing of coronary angiography.[21,79] In addition to the GRACE score, age (≥75 years), elevated Thrombolysis in Myocardial Infarction (TIMI) score, and cardiac biomarkers have also been shown to signal a higher risk for adverse events.[21,79] In high-risk patients with NSTE-ACS exhibiting a GRACE score above 140, adopting an early invasive strategy within 24 hours tends to reduce recurrent ischemia, diminish the necessity for urgent revascularization, and shorten hospital length of stay. Although clinical studies have not conclusively favored early (within 24 hours) over delayed invasive strategies for the entire NSTE-ACS population, analyses of specific high-risk subgroups within these studies support an early approach to intervention. Notably, the TIMACS (Timing of Intervention in Acute Coronary Syndromes) and VERDICT (Very Early Versus Deferred Invasive Evaluation Using Computerized Tomography) trials, which examined early intervention timing (within 24 hours or less and within 12 hours, respectively), revealed that early invasive management notably lessens cardiovascular complications in high-risk patients.[80–82]

Unstable Angina

USA is best described as existing along the continuum of NSTE-ACS, defined by one or more of the following criteria in patients whose cardiac marker levels do not meet criteria for AMI: prolonged rest angina (usually over 20 minutes); new-onset angina of at least Class 3 severity (symptoms with everyday living activities, e.g., moderate limitation such as walking one or two blocks on flat ground); or increasing angina that has become more frequent, severe, longer in duration, or lower in threshold.[81–83] Previously, guidelines recommended a conservative approach that focused on medical therapy (antiplatelet, anticoagulant and antianginal, β-blockers, and statins) and addressing modifiable risk factors (smoking cessation, physical activity, diet, etc.), followed by an evaluation for possible revascularization.[80–83] In these patients, angiography was typically performed within 24 hours of admission if stable (no evidence of very-high risk criteria) or immediately (<2 hours) if unstable (unabating symptoms, persistent arrhythmias, or hemodynamic instability). The choice of revascularization was then guided by angiography and other invasive strategies. However, the ischemia-guided strategy has since emerged, and evidence has demonstrated that USA/NSTE-ACS carries a higher risk of mortality compared with SIHD, with symptoms less likely to be resolved by guideline-directed medical therapy (GDMT) alone.[20,21] As such, early evaluation and possible reperfusion are recommended, especially in patients with a high GRACE risk score, high-sensitivity cardiac troponin measurements, and new ST-segment changes. The final decision for revascularization follows the same path as those for PCI versus CABG, as outlined in Fig. 111.5.[21,80–84]

INDICATIONS FOR REVASCULARIZATION: STABLE ISCHEMIC HEART DISEASE

It is important to understand that PCI and CABG restore myocardial blood flow by starkly different mechanisms. Whereas PCI specifically addresses individual, discrete stenoses, it does not halt the progression or rupture of plaques in the artery. Conversely, CABG not only improves blood flow in the affected area but also safeguards against damage from upstream and downstream plagues. Indeed, evidence supports that a certain subgroup of patients benefits from CABG in terms of survival and the risk of late spontaneous MI.[21]

TABLE 111.3 Other Indications for CABG

PATIENT STATUS	CLASS OF RECOMMENDATION COR 1 (BENEFIT >>> RISK)	COR 2A (BENEFIT >> RISK)	COR 2B (BENEFIT ≥ RISK)
Ventricular Arrhythmias			
	Patients with **VF, polymorphic VT, or cardiac arrest,** revascularization of significant CAD is recommended **to improve survival**		
Undergoing Other Cardiac Surgery			
	Patients **undergoing valve surgery, aortic surgery, or other cardiac operations** with significant CAD, CABG is recommended **to reduce ischemic events**	Patients undergoing **valve surgery, aortic surgery, or other cardiac operations** who have intermediate CAD, CABG may be reasonable **to reduce ischemic events**	

Note: CABG is indicated in patients with VF, polymorphic VT, or cardiac arrest to improve survival (COR 1). In patients with CAD who have a primary indication for valvular, aortic, or other cardiac surgery, CABG is recommended to reduce ischemic events (COR 1). *Revascularization* refers to PCI or CABG.

Data from Lawton JS, et al. 2021 ACC/AHA/SCAI Guideline for Coronary Artery Revascularization: a report of the American College of Cardiology/American Heart Association Committee on Clinical Practice Guidelnes. *J Am Coll Cardiol* 2022;79:e21-e129. Virani SS, Newby LK, Arnold SV, et al. 2023 AHA/ACC/ACCP/ASPC/NLA/PCNA guideline for the management of patients with chronic coronary disease: a report of the American Heart Association/American College of Cardiology Joint Committee on Clinical Practice Guidelines. *Circulation.* 2023;148(9):e12-e56. Content used with permission from the Journal of the American College of Cardiology (JACC).

The 2021 ACC/AHA/SCAI Guideline for Coronary Artery Revascularization for patients with SIHD details treatment in five main subsets of patients: those with LV dysfunction and multivessel CAD, those with left main disease, those with isolated multivessel disease, those with stenosis in the proximal LAD artery, and those with single- or double-vessel disease not involving the proximal LAD. The recommendations are summarized in Tables 111.2 and 111.3 and Fig. 111.6. In brief, there is a Class of Recommendation (COR) 1 recommendation for CABG in patients with multivessel (≥3 vessels) disease and severe LV systolic dysfunction (LVEF ≤35%) if they are otherwise good surgical candidates. Evidence shows that CABG is associated with improved odds of survival in these patients.[21] It is also reasonable (COR 2a) to choose CABG in patients with stable multivessel CAD who have mild to moderate LV systolic dysfunction (LVEF 35%–50%). This recommendation recognizes the importance of including a left internal mammary artery (LIMA)-to-LAD graft as a part of CABG.[21] In patients with SIHD and significantly stenosed left main artery, CABG is recommended (COR 1). However, PCI is reasonable in patients with SIHD and clinically significant left main stenosis if PCI can offer equivalent revascularization as CABG (COR 2a).[21] In patients with SIHD and multivessel CAD with normal ejection fraction with or without proximal LAD disease, CABG *may be* reasonable to improve survival (COR 2b).[21] In these patients, the usefulness of PCI to promote survival *remains uncertain.*[21,44,85]

Additionally, there is no benefit to coronary revascularization in patients with SIHD, normal LVEF, and one- or two-vessel CAD not involving the LAD (COR 3). Finally, revascularization is harmful in SIHD with ≥1 vessel CAD with <70% stenosis involving a non-LMCA (COR 3).[21]

Situations in Which Coronary Artery Bypass Graft Is Preferred Over Percutaneous Coronary Intervention to Improve Survival in Stable Ischemic Heart Disease

Three main goals have been identified in the management of patients with SIHD: symptom relief; prevention of adverse cardiac events, including nonfatal MI; and survival. CABG is preferred over PCI in patients with significant left main CAD and in patients with diabetes[86,87] to improve survival (both COR 1) and in patients with complex multivessel disease (COR 2a) to improve survival (see Table 111.2 and Fig. 111.6). These recommendations are based on data from the ISCHEMIA trial[44]; the FAME 2 trial[27]; and the 10-year updates from the Medicine, Angioplasty, or Surgery Study II (MASS II) trial,[88] which showed a reduction in cardiovascular mortality with surgical revascularization compared with optimal medical therapy (OMT) alone in these patients. In patients with CCD and complex three-vessel disease, a heart team approach is advocated, especially when there is a lack of clarity regarding the optimal treatment strategy.[21]

REVASCULARIZATION TO REDUCE VENTRICULAR ARRHYTHMIAS

In patients with ventricular arrhythmias, a thorough assessment for potential ischemic CAD is essential for decision-making by the heart team regarding the need for coronary artery revascularization.[89,90] Evidence from observational studies underscores that revascularization procedures in patients with life-threatening ventricular arrhythmias and those who have survived cardiac arrest are correlated with a notable decrease in arrhythmia frequency and improved survival. As such, the latest guideline

FIGURE 111.6 American College of Cardiology/American Heart Association/Society for Cardiovascular Angiography and Interventions (2021) evidence-based clinical decision pathway for revascularization in patients with SIHD. This detailed flowchart outlines the clinical decision-making process for the revascularization of patients with SIHD, focusing on symptomatic management and improvement of survival rates. It provides a systematic approach for determining when revascularization is indicated, differentiating between symptomatic relief and anatomic conditions that improve patient survival. The pathway considers the severity of symptoms, presence and extent of left main coronary artery disease, suitability for surgical or percutaneous interventions, and patient-specific factors such as EF and the presence of multivessel CAD. In sum, in patients with SIHD, the main indication for revascularization is to improve survival (right side of figure). There is one indication for revascularization to improve symptoms (left side of figure). Recommendations depicted in this figure are expanded in Tables 111.2 and 111.3. *CABG,* Coronary artery bypass graft; *CAD,* coronary artery disease; *EF,* ejection fraction; *GDMT,* guideline-directed medical therapy; *PCI,* percutaneous coronary intervention; *SIHD,* stable ischemic heart disease. From *Circulation* and the *Journal of the American College of Cardiology.* ©2022 American Heart Association, Inc.)

from the ACC/AHA/SCAI Guideline for Coronary Artery Revascularization offers a Class 1 recommendation for revascularization (with CABG or PCI) for patients with a history of cardiac arrest, polymorphic ventricular tachycardia, or ventricular fibrillation (Table 111.4).[21,89,90]

INDICATIONS FOR REVASCULARIZATION IN PATIENTS UNDERGOING OTHER CARDIAC SURGERY

In patients with CAD who have a primary indication for valvular, aortic, or other cardiac surgery, CABG is recommended to reduce ischemic events (COR 1) (see Table 111.4).[21]

MECHANICAL COMPLICATIONS OF ACUTE MYOCARDIAL INFARCTION

Mechanical complications after an AMI, such as left ventricular free-wall rupture, ventricular septal rupture, PMR, pSA, and true aneurysm, are rare but significant complications that may be seen in modern cardiovascular practice.[91–93] Before the coronavirus pandemic, the incidence of these complications was low, averaging between 0.27% and 0.9% of all AMI cases. [91–93] However, there are reports suggesting an increase in the incidence of these complications during the pandemic, likely due to the pandemic-associated delay in seeking medical care, including delays in timely ACS-related interventional procedures.[94,95] Notably, despite this low incidence, the mortality associated with these complications remains high.[96] CABG is indicated for patients with any of these complications according per the 2021 ACC/AHA/SCAI Guideline for Coronary Artery Revascularization (COR 1).[21]

Left Ventricular Pseudoaneurysm

An LV pSA is caused by the rupture of the ventricular wall that remains contained by the pericardium and fibrous tissue. There is no component of LV wall in the aneurysm, and it is essentially a contained free rupture. Patients may present with dyspnea, sudden chest pain, or cardiac tamponade, which may manifest as late as 50 days, although about a third of patients present within 2 weeks after an MI.[61] True LV aneurysm, a noncontractile outpouching of the ventricle with all layers of the myocardial wall, is rare because of the advent of rapid revascularization.[97] In patients with ACS and LV pSA, CABG is recommended (COR 1).[21]

Ventricular Septal Defect

Delay in reperfusion is associated with an increased risk of VSD formation. A bimodal pattern of occurrence has been described—within the first 24 hours and again between 3 and 5 days after MI. Two trials, the Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock (SHOCK) trial registry[98] and the Global Utilization of Streptokinase and TPA for Occluded Coronary Arteries I (GUSTO-I) trial,[99] found deviations from this described timeline, finding that the median time for VSD development was 16 hours and 1 day, respectively. Notably, female sex, advanced age, and chronic kidney disease (CKD) have been suggested as risk factors for MI-associated VSD. Ironically, the absence of hypertension, diabetes, smoking, or prior history of MI is also associated with an increased risk of VSD.[100] In

TABLE 111.4 **2021 ACC/AHA/SCAI Evidence-Based Recommendations for Conduit Selection for CABG**

CONDUIT TYPE	RECOMMENDATION
Radial artery for CABG	1. In patients with CAD who might require future revascularization, avoid unnecessary radial artery instrumentation/catheterization. 2. Preserve the radial artery for future use as a conduit by avoiding bilateral radial artery procedures in CAD patients. 3. Avoid the use of the radial artery in patients with chronic kidney disease who may progress to requiring hemodialysis. 4. Avoid the use of the radial artery after transradial coronary angiography. 5. Assess the palmar arch for completeness and ulnar compensation before harvest. 6. Use the upper extremity with the best ulnar compensation for radial artery conduit. 7. Target subocclusive stenosis with radial artery grafts. 8. Administer oral calcium channel blockers for 1 year after radial artery grafting.
Bilateral internal mammary artery in CABG	Use skeletonization technique for IMA harvest to reduce the risk of sternal wound infection.
Saphenous vein for CABG	1. Endoscopic harvesting technique should be employed in patients at high risk for wound complications. 2. No-touch saphenous vein harvesting may be used in patients at low risk for wound complications.
Gastroepiploic artery for CABG	Skeletonization should be used when the gastroepiploic artery is chosen as conduit for grafting the right coronary artery with subocclusive stenosis (operator dependent).

Note: Preserving the radial artery as a future conduit for CABG is important in patients with CKD or known CAD who might require surgical revascularization in the future. This includes the avoidance of bilateral radial artery instrumentation or catheterization in at-risk patients. Preoperative evaluation for conduit selection is critical, including physical exam to assess for adequate ulnar compensation to permit safe radial artery harvesting. The use of endoscopic techniques to harvest the saphenous vein is recommended in patients at high risk of wound complications. Finally, the role of skeletonization is discussed with regard to BIMA and gastroepiploic artery grafting.

patients with ACS complicated by a VSD, CABG is recommended (COR 1).[21]

Papillary Muscle Rupture With Mitral Regurgitation

Although it has an incidence of 0.05% to 0.26%, PMR is implicated in more than 50% of observed cases of severe mitral regurgitation after AMI, with reported mortality rates of 10% to 40%.[97,101] Usually, PMR manifested within 7 days after an MI, with a median presentation of 13 hours, in the SHOCK trial.[98,102] Notably, PMR was more likely to occur in older patients and in patients with a history of heart failure, CKD, and first AMI presentation. An inverse relationship was found between having diabetes and prior MI and developing PMR.[96,101] Notably, for ACS patients with PMR and mitral regurgitation, CABG is recommended to improve survival (COR 1).[21]

INDICATIONS FOR REVASCULARIZATION IN PATIENTS WITH CHRONIC CORONARY DISEASE

Chronic coronary disease (CCD) (also known as *chronic coronary syndrome*) describes a broad range of conditions where coronary arteries are unable to supply adequate blood to the myocardium as a result of atherosclerosis. Patients may be symptomatic or asymptomatic. This condition is different from the previously addressed stable ischemic disease, which is used specifically to characterize patients with a stable and predictable pattern of angina (pain, discomfort, pressure, or other anginal-equivalent symptoms) that is usually exacerbated with physical exertion and is relieved with rest or medication. The spectrum of patients defined to have CCD includes[21,103]:

1. Patients who have been discharged after an admission for an ACS event or after undergoing coronary revascularization, once all acute cardiovascular complications have been stabilized
2. Individuals presenting with LV systolic dysfunction, who have known or suspected CAD, or who suffer from ischemic cardiomyopathy
3. Patients experiencing stable angina symptoms or ischemic equivalents, such as dyspnea or arm pain upon exertion, who are under medical management irrespective of the outcomes of any imaging tests
4. Individuals with symptoms indicative of coronary vasospasm or microvascular angina
5. Patients diagnosed with CCD based exclusively on the results of screening studies, such as stress tests or coronary CTA

The 2023 AHA/ACC/American College of Clinical Pharmacy (ACCP)/American Society for Preventive Cardiology (ASPC)/National Lipid Association (NLA)/Preventive Cardiovascular Nurses Association (PCNA) Guideline for the Management of Patients with CCD has the same recommendations for CABG as in the 2021 ACC/AHA/SCAI Guideline for Coronary Artery Revascularization summarized earlier.

PREOPERATIVE EVALUATION FOR CORONARY ARTERY BYPASS GRAFTING

As previously discussed, the involvement of a heart team (consisting of the heart surgeon, interventional cardiologist, and noninterventional cardiologist, with additional involvement, when necessary, of the primary care physician, imaging specialists, cardiac anesthesiologist, intensivist, heart failure specialists, palliative care experts, physical and occupational therapists, and/or nursing staff) is recommended (COR 1) in the assessment and deliberative process regarding coronary revascularization in patients for whom the optimal treatment strategy is unclear. Discussions should always include the patient's goals and preferences and the addition of family members as appropriate.[21]

Preoperative assessment begins with a thorough history and physical exam, including assessment of physical and mental health status, current medications (especially those that interfere with cardiac function or coagulation/platelet function), socioeconomic stressors, and prior surgeries. A directed cardiovascular exam should include carotid auscultation, lung and heart auscultation, and evaluation of extremity pulses. The STS PROM should be calculated (COR 1) and includes comorbidities such as age; sex; elective versus emergency status of operation; LVEF; tobacco use; diabetes; hypertension; stroke; peripheral vascular disease (PVD); chronic lung disease; prior kidney disease; use of immunosuppressants; and previous cardiac surgeries, including prior revascularization.[21] This score will assist in treatment recommendations and in the appropriate informed consent in the discussion of risks and benefits of CABG with the patient.[21]

Careful review of CXR, TTE, and cardiac catheterization results is necessary to determine candidacy for CABG. Additional testing, including bilateral lower extremity venous mapping, ultrasound of RAs, carotid duplex evaluation, CT scan of the chest, or other imaging, may be warranted depending on the physical exam findings. Many of the diagnostic tests mentioned in previous sections provide valuable data for determining the appropriateness of medical therapy alone, PCI, or CABG. At each stage of the evaluation process, maintaining equity and a shared decision-making strategy is important.[21] A meticulous preprocedural heart team assessment is so crucial that it earned a COR 1 endorsement in the 2021 ACC/AHA/SCAI Guideline for Coronary Artery Revascularization.[21]

TECHNIQUE OF MYOCARDIAL REVASCULARIZATION: CONVENTIONAL ON-PUMP CARDIOPULMONARY BYPASS

The use of conventional cardiopulmonary bypass (CPB) in CABG involves a series of critical steps and components that ensure the safe and effective management of cardiac procedures. Initiation of CPB is a pivotal process in major cardiac surgeries, involving the diversion of venous blood from the body to a heart-lung machine, which then oxygenates and returns this blood in a controlled, pressurized manner.[104–106] Essentially, this process bypasses most blood flow to the heart and lungs, allowing surgeons the ability to operate in a quiet, bloodless field.

The extracorporeal CPB circuit consists of several basic components: venous cannula, tubing, reservoir, oxygenator, pump (centrifugal or roller head), filter, tubing, and arterial cannula. Venous cannulas are used to drain returning deoxygenated venous blood, which collects in a venous reservoir by gravity. This can be augmented by raising the operating room table or via addition of suction. The circuit includes an oxygenator and heat exchanger, a perfusion pump, a blood filter in the arterial line, and an arterial cannula. These blood conduits are designed to minimize turbulence, cavitation, and changes in blood flow velocity, which could harm the integrity of blood cells. The circuit also contains a dead space and necessitates a priming solution to initiate the pump and tubing, usually comprising either a balanced salt solution or, often, a starch solution. Homologous blood or fresh frozen plasma may be added as needed.[107]

Additional components include cardiotomy suction devices and tubing for infusion of cardioplegia or other solutions that may be used. A cardiotomy suction system collects blood from open cardiac chambers and the surgical field, which is then filtered, de-aired, and returned to the bypass circuit. A cardioplegia infusion device, comprising a separate pump, reservoir, and heat exchanger, delivers cold, potassium-enriched blood or crystalloid solutions into the coronary circulation for cardiac arrest and myocardial protection.

The use of CPB necessitates adherence to stringent anticoagulation protocols because of the high thrombogenic potential of the tubing and bypass pump components. Heparin is most commonly used, with strict monitoring of the activated clotting time (ACT) to ensure effective anticoagulation throughout the procedure. The common practice involves administering an initial bolus of heparin before cannulating the patient for CPB. This dose typically ranges from 300 to 400 units per kilogram (U/kg) of the patient's body weight. The goal is to achieve an ACT of greater than 400 seconds, which is considered adequate for safe initiation of CPB. ACT is monitored regularly during CPB. If the ACT falls below a certain threshold (approximately 400 seconds), additional heparin is administered. Subsequent additional doses or a heparin infusion is dosed according to ACT level.

Procedural Steps for On-Pump Coronary Artery Bypass Grafting With Cardioplegic Arrest

The procedural sequence for CABG with cardioplegia encompasses a series of meticulously executed steps. Initially, surgical access is gained through a median sternotomy, followed by the harvesting of the conduit. Before cannulation, the patient undergoes systemic heparinization. Cannulation is then performed to establish the CPB circuit. CPB is initiated after a series of checklist items is confirmed by the perfusionist. Once CPB commences, the surgical team evaluates potential sites for distal coronary anastomoses. The application of a cross clamp precedes the administration of cardioplegia, which facilitates a quiescent heart for performing the distal anastomoses. Cardioplegia is given in the antegrade fashion, directly into the aortic root, and infuses the coronary arteries (with a competent aortic valve) or in the retrograde fashion, via a catheter in the coronary sinus (Fig. 111.7). Intermittent cardioplegia, typically every 20 minutes, is administered to maintain myocardial protection. Proximal anastomoses are then completed. After this, the cross clamp is removed, and mechanical ventilation is resumed. The weaning process from CPB begins, followed by the administration of protamine for heparin reversal. Flow in the newly constructed conduits is assessed before decannulation. Decannulation, judicious hemostasis, and subsequent sternal closure occur. It is noteworthy that the sequence of these steps can vary, with alternatives including the initial performance of proximal anastomoses or the use of a partial occluding aortic clamp for proximal anastomoses. Thorough preoperative planning is imperative to ensure optimal surgical outcomes.[5]

Conduit Selection for Coronary Artery Bypass Grafting

Conduit selection for CPB is a critical step in planning for CABG. Saphenous vein grafts (SVGs) have been associated with lower long-term patency rates compared with arterial grafts in several studies.[108–112] Long-term graft patency is correlated with survival[108,113–115]; thus, cardiac surgeons must carefully consider these choices at the time of preoperative evaluation. The most common conduits for CABG are the LIMA and right internal mammary artery (RIMA), SVG, RA, and any combination of these. The gastroepiploic artery, although historically described, is rarely used in modern practice in the United States. Table 111.4 provides a summary of society-based guidelines for CABG conduit selection.

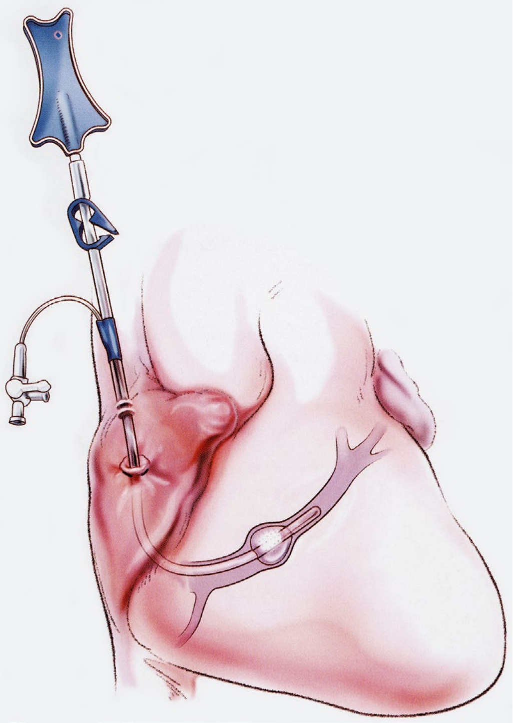

FIGURE 111.7 Depiction of coronary sinus cannulation. Illustration of retrograde cardioplegia delivery via a catheter inserted into the coronary sinus. As an alternative to antegrade cardioplegia, the cardioplegia solution is administered against the normal direction of blood flow and can ensure a uniform and effective distribution of cardioplegia throughout the myocardium, particularly in patients with proximal disease in multiple coronary arteries. The retrograde cardioplegia catheter is advanced with care into the right atrium and the coronary sinus via palpation and with transesophageal echocardiography assistance. By placing the left hand on the cannula and the right hand on the inferior vena cava (IVC), the cannula can be felt at the IVC and then directed toward the patient's left shoulder for insertion into the coronary sinus. (From Buxton B, Frazier OH Westaby S, eds. *Ischemic Heart Disease Surgical Management.* London: Mosby Ltd.; 1999. Illustrations by Elizabeth D. Croce. Used with permission.)

Left Versus Right Internal Mammary Artery

For many decades, grafting the LIMA to the LAD has been the gold standard in surgical revascularization and an important STS quality metric. This stems from evidence documenting superior patency and long-term survival benefits of using the LIMA regardless of sex, age, diabetes, hypertension status, LVEF, and NYHA class.[111,116–118] Although some studies have found superior long-term patency of LIMA to LAD, defined as $<$80% stenosis of the LIMA at 20 years compared with right internal thoracic artery (RITA)-to-LAD grafts (96.3% vs. 88.1%), others have found equivalent patency rates between the two.[112,119] Overall, the use of any internal mammary artery (IMA) over SVG is associated with reduced mortality, need for revascularization, and rehospitalization for cardiac events.[111,115,119–124] Therefore, in patients undergoing

CABG for CAD that includes the LAD, the use of an IMA, especially the LIMA, carries a Class 1 ACC/AHA/SCAI recommendation to improve survival and reduce ischemic events.[21]

The right IMA carries the same recommendation (COR 1) in the current ACC/AHA/SCAI Guideline for Coronary Artery Revascularization.[14] In situations where the LIMA is not usable, the RIMA may be used to graft the LAD. Additionally, both IMAs may also be used. Multiple meta-analyses of observational studies have demonstrated longer survival with bilateral IMA (BIMA) grafting than with single IMA (SIMA) use.[121,125,126] In one network meta-analysis, RIMA emerged as the second-best conduit in CABG because of its reported 27% absolute risk reduction in late functional graft occlusion.[122]

The Arterial Revascularization Trial (ART) is, to date, the most extensive RCT evaluating the benefits of BIMA versus SIMA. With 3102 patients randomized to either SIMA (n = 1554) or BIMA (n = 1548), the primary outcome was all-cause mortality. At the 10-year evaluation, no intergroup statistically significant mortality benefits were observed with either strategy.[126] Although this was a significant and somewhat unexpected finding, the high rate of crossover (14% from BIMA to SIMA, and 22% of patients in LIMA group also had an RA graft) and surgeon experience may have played a role. When an "as-treated" analysis was performed, outcomes were better in the BIMA group compared with a single artery cohort. Notably, these benefits appeared to be more pronounced in diabetic patients and those 70 years or younger.[127,128]

Saphenous Vein Grafts

Compared with LIMA-to-LAD grafting, the patency rate of SVG-to-LAD graft lags significantly, ranging from 70% to 87% within 1 year, with a dramatic drop to approximately 50% at 10 years.[111,112] Early SVG failure is related to technical reasons. Long-term SVG failure has been linked to significant obstruction due to neointimal hyperplasia. Despite the best attempts to attenuate this phenomenon with the use of statins and β-blockers, LIMA grafting continues to demonstrate significant superiority compared with SVG.[108,110–112] The use of the no-touch SVG strategy appears to be showing promising results with regard to graft patency.[129]

Radial Artery Grafts

Although Carpentier et al. (1973) described the short-term benefits of the use of RA graft in aorta-to–coronary artery bypass over SVG, concerns regarding competitive flow, arterial spasm, and early occlusion made this practice unpopular for decades.[130] In an effort to increase the use of multiarterial conduits for coronary revascularization, many studies (including pooled analysis from six RCTs) have documented the benefits of radial arterial grafting. RA patency competed favorably with the IMA at 1, 5, and 10 years.[131–134] A 2018 meta-analysis by Gaudino et al. aimed to compare the outcomes of RA versus SVGs.[134] They included 1036 patients (502 with SVG vs. 534 with RA grafts). The primary outcome was a composite of death, MI, or repeat revascularization. The secondary outcome focused on graft patency. At 5 years, RA grafts resulted in a lower rate of adverse cardiac events and a higher patency rate compared with SVGs.

Additionally, the recently published 15-year results of the RAPCO (Radial Artery Patency and Clinical Outcomes) randomized trials that compared the outcomes of MACEs of CABG using the RA, RITA, or SVG[135] noted that the incidence of MACE was significantly lower in patients treated with RA graft versus RITA (39.4% vs. 48.5%; HR = 0.74, 95% CI 0.55–0.97, P = 0.04). Mortality rates were 22.2% (RA) and 30.1% (RITA) (HR = 0.69, 95% CI 0.47–1.02). The rate of MACE was 60.2% in RA versus 73.2% in saphenous vein (SV) (HR = 0.71, 95% CI 0.52–0.98, P = 0.04). Mortality rates were 52.2% (RA) and 63.4% (SV) (HR = 0.74, 95% CI 0.52–1.04). The 2021 ACC/AHA/SCAI Guideline on Coronary Artery Revascularization has given a Class 1 recommendation for the use of an RA as the conduit of choice, over an SVG, to graft the second most important, significantly stenosed non-LAD vessel to improve long-term cardiac outcomes (see Table 111.4).[21]

Bilateral Internal Mammary Arterial Grafts

The use of BIMA grafts in CABG has garnered support from various observational studies and meta-analyses. A meta-analysis of 27 studies (no RCT) with 79,063 patients (including 19,277 BIMA and 59,786 LIMA cases) found long-term survival benefits in the use of BIMA versus SIMA.[136] In contrast, a large-scale RCT consisting of 3102 patients (the ART) showed no difference in 10-year all-cause mortality or the composite outcome of death, MI, or stroke when comparing BIMA with SIMA, as stated earlier.[126] Notably, in this study, there was a high crossover rate (14% from BIMA to SIMA, and 22% receiving an RA in the SIMA group). An as-treated analysis indicated improved survival with multiple arterial grafts. Further, increased BIMA use correlated with protocol adherence, highlighting the importance of surgical expertise. However, low institutional BIMA volumes were associated with higher operative mortality.[126]

Other studies and meta-analyses advocate for ≥3 arterial grafts, including total arterial revascularization, but the increased risk of sternal infection with BIMA (particularly in diabetes, obesity [BMI >30 kg/m^2], and immunosuppressed patients) has led to caution with the use of BIMA.[127,137] Interestingly, skeletonization appears to reduce the risk of sternal wound infection while preserving the known benefits of BIMA in diabetic patients. Currently, there is a Class 2a recommendation in the 2021 ACC/AHA/SCAI Guideline for Coronary Artery Revascularization for the use of BIMA in carefully selected patients by experienced cardiac surgeons.[21]

Evidence-Based Practice Guidelines for Conduit Selection in Coronary Artery Bypass Grafting

The choice of conduits for CABG involves the careful consideration of several clinical and technical factors, including but not limited to patient comorbidities, life expectancy, degree of coronary artery stenosis, number of diseased vessels, and the operator's expertise and experience with various conduits. Table 111.4 summarizes the best-practice recommendations of the 2021 ACC/AHA/SCAI Guideline for Coronary Artery Revascularization.[21]

Technical Aspects of Coronary Artery Bypass Grafting

CABGs can be constructed using a variety of configurations (Figs. 111.8–111.9). Traditionally, the most common was LIMA to LAD (which is an STS quality measure) and SVG to the other left-sided vessels and right vessel (see Fig. 111.8). Because multiarterial grafting (MAG) provides many benefits, including prolonged survival, the current ACC/AHA/SCAI Guideline for Coronary Artery Revascularization supports the use of the RA (COR1) and the RIMA (COR 2a) over SVG. Common MAG configurations include combinations of BIMA and radial grafts to provide CR (see Fig. 111.9).

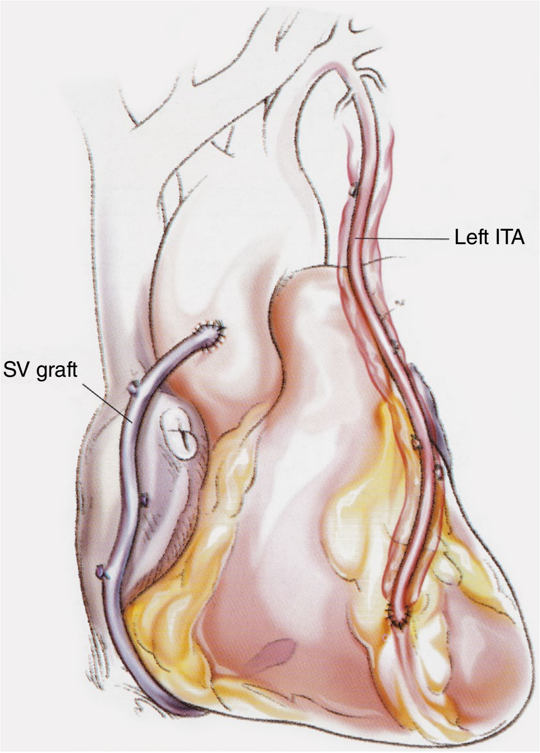

FIGURE 111.8 Common coronary artery bypass grafting configuration with left ITA and vein. The left ITA is anastomosed to the LAD, a technique favored for its high success and long-term patency rates. The image also displays the use of an SV vein graft from the aorta to the RCA. *LAD,* Left anterior descending artery; *ITA,* internal thoracic artery; *RCA,* right coronary artery; *SV,* saphenous vein. (From Buxton B, Frazier OH Westaby S, eds. *Ischemic Heart Disease Surgical Management.* London: Mosby Ltd.; 1999. Illustrations by Elizabeth D. Croce. Used with permission.)

Care should be taken to ensure proper conduit length so that the graft will reach the aorta or other proximal sites without kinking or bowstringing. Filling the heart while sizing is one method to measure length. Left-sided bypass grafts originating on the aorta travel beneath the LIMA graft and must have ample length even after the pulmonary artery is full and the heart is full and beating.

The order of performing the distal and proximal anastomoses is by surgeon preference (all distals first, then proximals; each distal and then proximal; or proximals and then distals). Distal anastomoses can be constructed in an end-to-side or side-to-side fashion using a running monofilament polypropylene suture (Figs. 111.10–111.11). Care is taken to ensure that the suture bites are full thickness, with the needle perpendicular to the conduit or target.

Proximal anastomoses may originate on the ascending aorta (Fig. 111.12), on the hood of another proximal, on the innominate artery, as a T or Y graft from another conduit, or rarely, on the descending aorta.

OFF-PUMP CORONARY ARTERY BYPASS GRAFTING

Off-pump CABG (OPCABG) is often regarded as an alternative surgical strategy to performing conventional CABG to circumvent the serious complications associated with CPB and cardioplegic arrest. It is typically considered in patients deemed at high risk for CABG due to porcelain aorta, reduced LVEF, severe chronic obstructive pulmonary disease, or recent MI. Another rationale behind this approach is to prevent further myocardial injury from the global myocardial ischemia, given that it is imposed during CABG with cross-clamp placement.

There are key distinctions between on-pump CABG and OPCABG. OPCABG necessitates specific adjuncts to facilitate manipulation of the heart to provide adequate exposure of coronary vessels, primarily because the heart remains contractile throughout the operation to support systemic perfusion. Both pleural spaces are often opened to facilitate rotation of the heart, enhance visibility of target areas, and reduce hypotension, particularly when working on the lateral and inferior myocardial walls. Unlike on-pump CABG, in OPCABG, the heart continues to eject and supply the brain and body with blood, and the lungs must continue to provide oxygenation to the blood. The most critical myocardial territory is revascularized first (e.g., LAD) to reduce ischemia while constructing subsequent anastomoses and to promote myocardial reserve. After this, remaining impacted segments of the heart are revascularized. Typically, revascularization begins with mammary artery–based pedicles because these do not necessitate a proximal anastomosis and immediately restore coronary blood flow to the bypassed vessel.[24,138–141]

For each target vessel, a small section of the coronary artery is exposed proximally to the intended anastomosis site, allowing for the placement of vessel loops or clamps for the occlusion of inflow. Additionally, a coronary shunt may be used. There are two types of stabilizers employed in OPCAB procedures, both of which use suction to attach to the heart. A fork-type stabilizer uses two adjustable suction arms that straddle the coronary target, making it largely immobile. Another padded mobile suction cup (moves with the motion of the heart) is applied to the apex of the heart for its manipulation and positioning throughout the procedure. Both suction devices may be attached to any portion of the sternal retractor. Manipulation of the operative table often facilitates the procedure, particularly the use of Trendelenburg position. The most difficult exposure to achieve is the lateral wall vessels, which may result in temporary mitral regurgitation while the heart is elevated. A sling on the posterior pericardium may be used to enhance visualization while elevating the heart. A lower target ACT may be used than that required for on-pump CABG. Close coordination with cardiac anesthesia colleagues is necessary for success in this method of coronary revascularization.

Multiple randomized clinical trials have raised concerns about OPCABG, particularly regarding higher rates of incomplete revascularization and reduced long-term survival. In 2022, the 10-year follow-up of the Veterans Affairs Randomized On/Off Bypass (ROOBY) trial showed no benefits in patients who received OPCABG. The median time to the composite end point of death for the off-pump group was shorter (4.6 years vs. 5 years, interquartile range [IQR] 1.8–7.9, $p = 0.03$) compared with the on-pump bypass patients.[140] Because of these results, OPCABG has waned in clinical practice. However, it has equivalent results in the hands of experienced off-pump surgeons and is useful in patients with porcelain aorta, in other high-risk patients, and in minimally invasive CABG procedures.[138,140,141]

ON-PUMP BEATING-HEART CORONARY ARTERY BYPASS GRAFTING

On-pump beating-heart CABG (ON-BH CABG) is another surgical option in high-risk patients. Using this method, hemodynamic

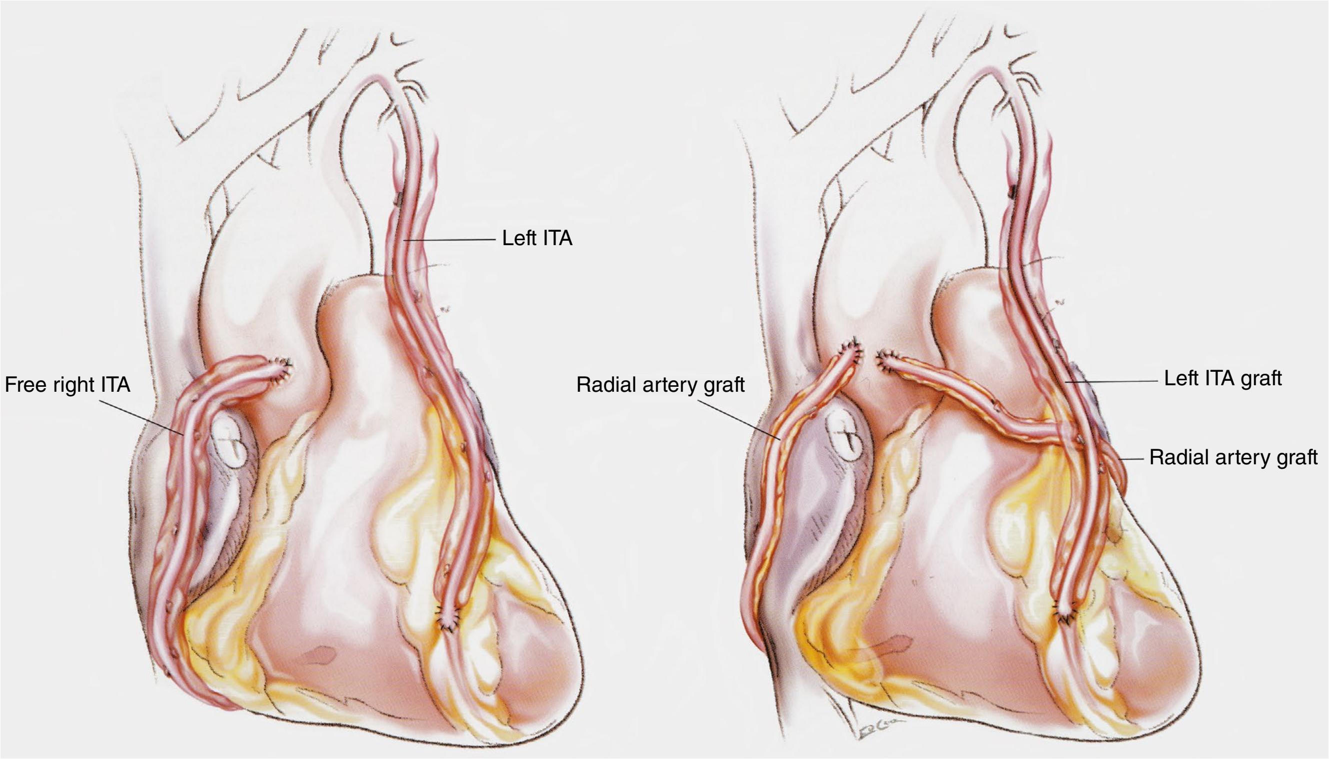

FIGURE 111.9 Common coronary MAG configurations. (A) In situ LITA graft and free right ITA originating on the aorta. (B) In situ LITA graft and free radial artery from the aorta to the obtuse marginal branch and free radial artery from the aorta to the distal RCA. *ITA,* internal thoracic artery; *LITA,* left internal thoracic artery; *MAG,* multiple arterial bypass grafting; *RCA,* right coronary artery. stability is maintained while effective exposure to the target coronary artery is achieved. This innovative technique aims to optimize coronary artery revascularization while mitigating some of the known hematologic and neurologic complications of on-pump CABG with cardioplegic arrest and global myocardial ischemia.[142]

A systematic review by Wang et al. (2021) evaluated 24 studies with 6862 patients (1847 ON-BH CABG and 5015 CABG) and found that CABG, compared with ON-BH CABG, had higher early mortality (odds ratio [OR] 1.45, 95% CI 1.09–1.93, p = 0.01), MI (OR 2.60, 95% CI 1.41%–4.78%, p <0.01), more low-output syndrome (OR 2.56, 95% CI 1.55–4.23, p <0.01), and more renal failure (OR 1.84, 95% CI 1.38–2.44, p <0.01). In high-risk patients, ON-BH CABG showed lower risks in terms of early mortality, intraaortic balloon pump (IABP) usage, renal failure, hemodialysis requirement, MI, and pulmonary complications.[142] This approach remains helpful in high-risk patients with bleeding dyscrasias, in those with low LVEF, and in patients with a porcelain aorta who require multivessel revascularization.

MINIMALLY INVASIVE DIRECT CORONARY ARTERY BYPASS

Minimally invasive direct coronary artery bypass (MIDCAB) grafting is a key alternative to conventional CABG, particularly for patients with isolated significant LAD stenosis for which PCI is not suitable.[143,144] The most common incisions used in MIDCAB include anterolateral thoracotomy, mini-sternotomy, and subxiphoid. MIDCAB, which integrates the principles of OPCABG and minimally invasive surgery, has generated interest because of its potential benefits, but concerns remain about the technical quality of anastomoses performed. A meta-analysis consisting of 2885 patients from 12 studies (6 RCTs, 6 observational trials [OTs]) compared the clinical outcomes of PCI versus MIDCAB in 2015. Pooled-effects estimate demonstrated an increased incidence of major adverse cardiac and cerebrovascular events (MACCEs) after PCI (OR 1.98, 95% CI 1.45–2.69, p <0.0001) at 6 months compared with MIDCAB.[143] There were no differences in the rate of postoperative stroke, MI, and all-cause mortality. However, patients in the PCI arm experienced shorter postoperative length of stay (weighted mean difference –3.37 days, 95% CI –4.92 to –1.81, p <0.0001). Of note, more patients in the PCI cohort had the LAD as the target artery than those in the MIDCAB arm (60.7% vs. 39.3%). A single-center retrospective study analyzed 1033 patients (303 MIDCAB and 730 drug-eluting stents [DES]-PCI) with isolated proximal LAD anastomosis, using propensity matching to assess short- and long-term (10-year) mortality and revascularization rates. Comparable short-term (30-day) mortality was noted between groups (0.6% vs. 0.3%, p = 0.99). However, after 10 years, patients with DES-PCI had a 2.2%-fold increased risk of late death, a twofold increased risk of repeat revascularization, and a 2.1%-fold higher risk of composite death and revascularization (95% CI 1.41–3.24) compared with the MIDCAB cohort.[145]

A more recent meta-analysis involving 3847 patients evaluated the 20-year outcome of MIDCAB versus PCI. This study found higher short-term mortality in MIDCAB patients based on six

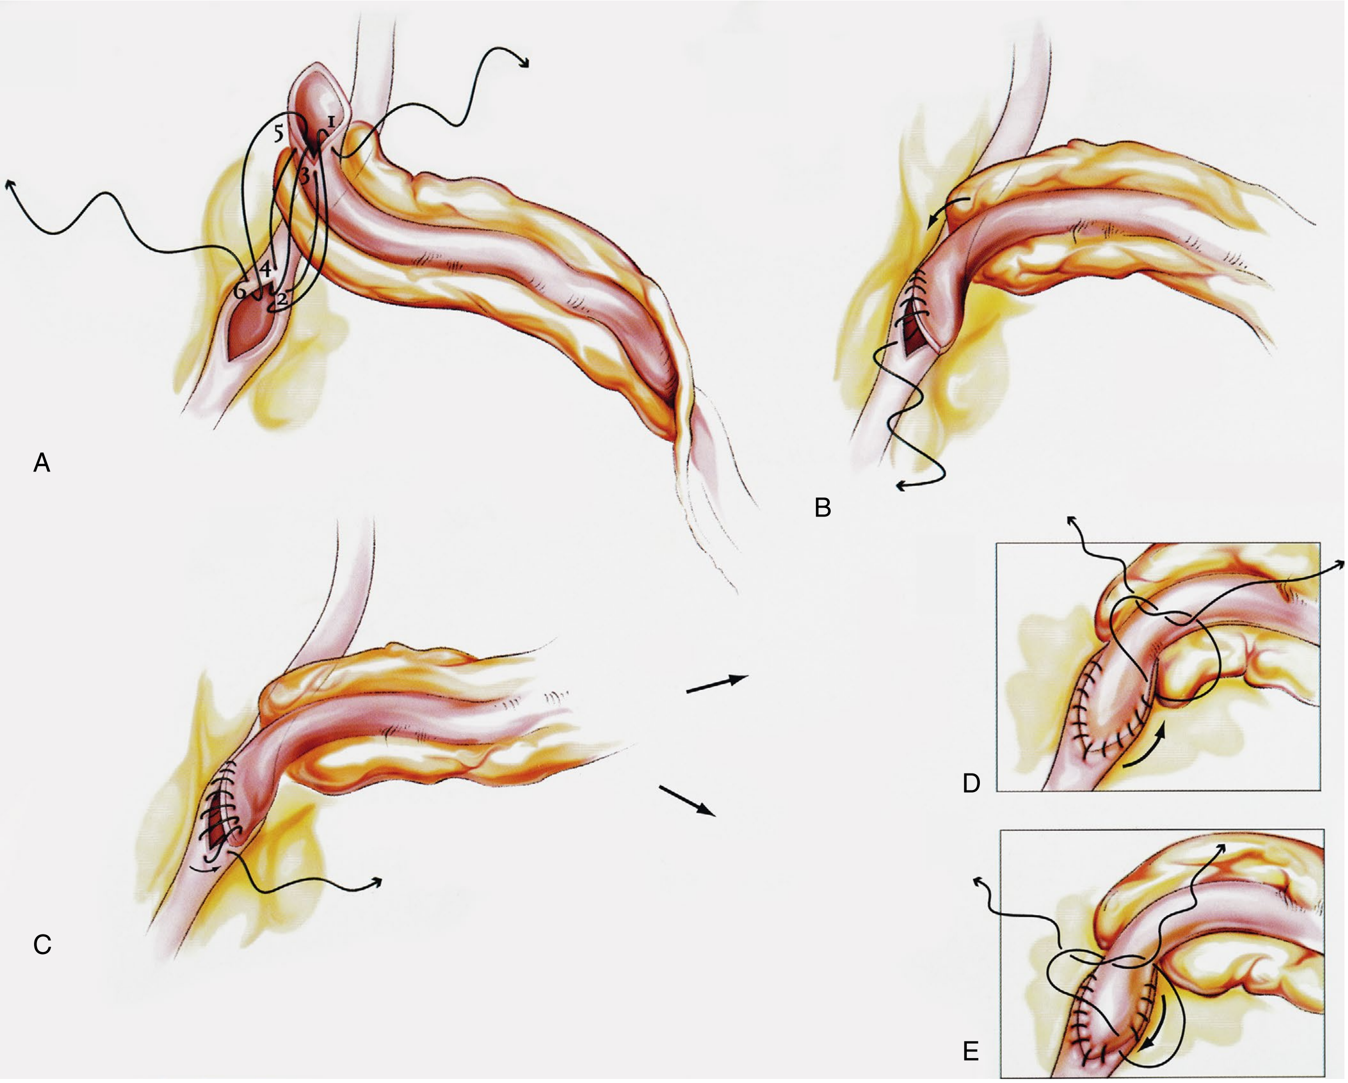

FIGURE 111.10 Distal coronary artery bypass grafting with end-to-side anastomosis. (A) Heel sutures begin with outside-in (backhand) suturing in the conduit and inside-out (backhand) suturing in the coronary. (B) Forehand suturing down the side of the anastomosis. (C) Forehand suturing around the toe, with extreme care to avoid the back wall of the coronary at the toe of the anastomosis. (D) Backhand suturing along the right side of the anastomosis and tie near heel. (E) Alternative to D; forehand suturing using other end of suture down the right side of the anastomosis and tie near toe. This requires suturing outside in on the coronary, which is not recommended with friable, calcified wall. (From Buxton B, Frazier OH Westaby S, eds. *Ischemic Heart Disease Surgical Management*. London: Mosby Ltd.; 1999. Illustrations by Elizabeth D. Croce. Used with permission.)

RCTs (RR 7.30, 95% CI 1.38–38.6, number needed to treat [NNT] 100), but at midterm and long-term follow-up, no difference in cardiac mortality was found. With regard to rate of TVR, MIDCAB performed better. However, the authors reported possible publication bias as the reason for the observed short-term mortality differences.[146] The 2021 ACC/AHA/SCAI Guideline for Coronary Artery Revascularization recommends further research focused on the use of nonsternotomy incisions for CABG.[21]

ROBOTIC TOTALLY ENDOSCOPIC CORONARY ARTERY BYPASS

Since the first totally endoscopic coronary artery bypass (TECAB) surgery in 1998, many centers have reported mixed results.[147] The most popular platform includes a surgeon-device interface, a controller (computer), and patient interface with surgical instruments. A 2019 systematic review of 2397 patients over two decades noted a decreasing trend in the conversion rate from beating-heart TECAB to traditional CABG (from ∼50% to 9.3%), decreased mean percentage early postoperative mortality of 1.1%, stroke rate of 0.4%, 2% incidence of renal failure, and 3.8 days median length of stay.[147] Interestingly, the rate of conversion in arrested-heart (AH)-TECAB was 13.3%, and the median operative time of AH-TECAB was 305 (112–1050 minutes) versus 279 (177–373 minutes) in conventional CABG patients. The postoperative mortality was 0.6% in patients with AH-TECAB, with median stroke and renal failure incidences of 1.5% and 1.3%, respectively. Compared with outcomes in the Future Revascularization Evaluation in Patients With Diabetes Mellitus: Optimal Management of Multivessel Disease (FREEDOM)

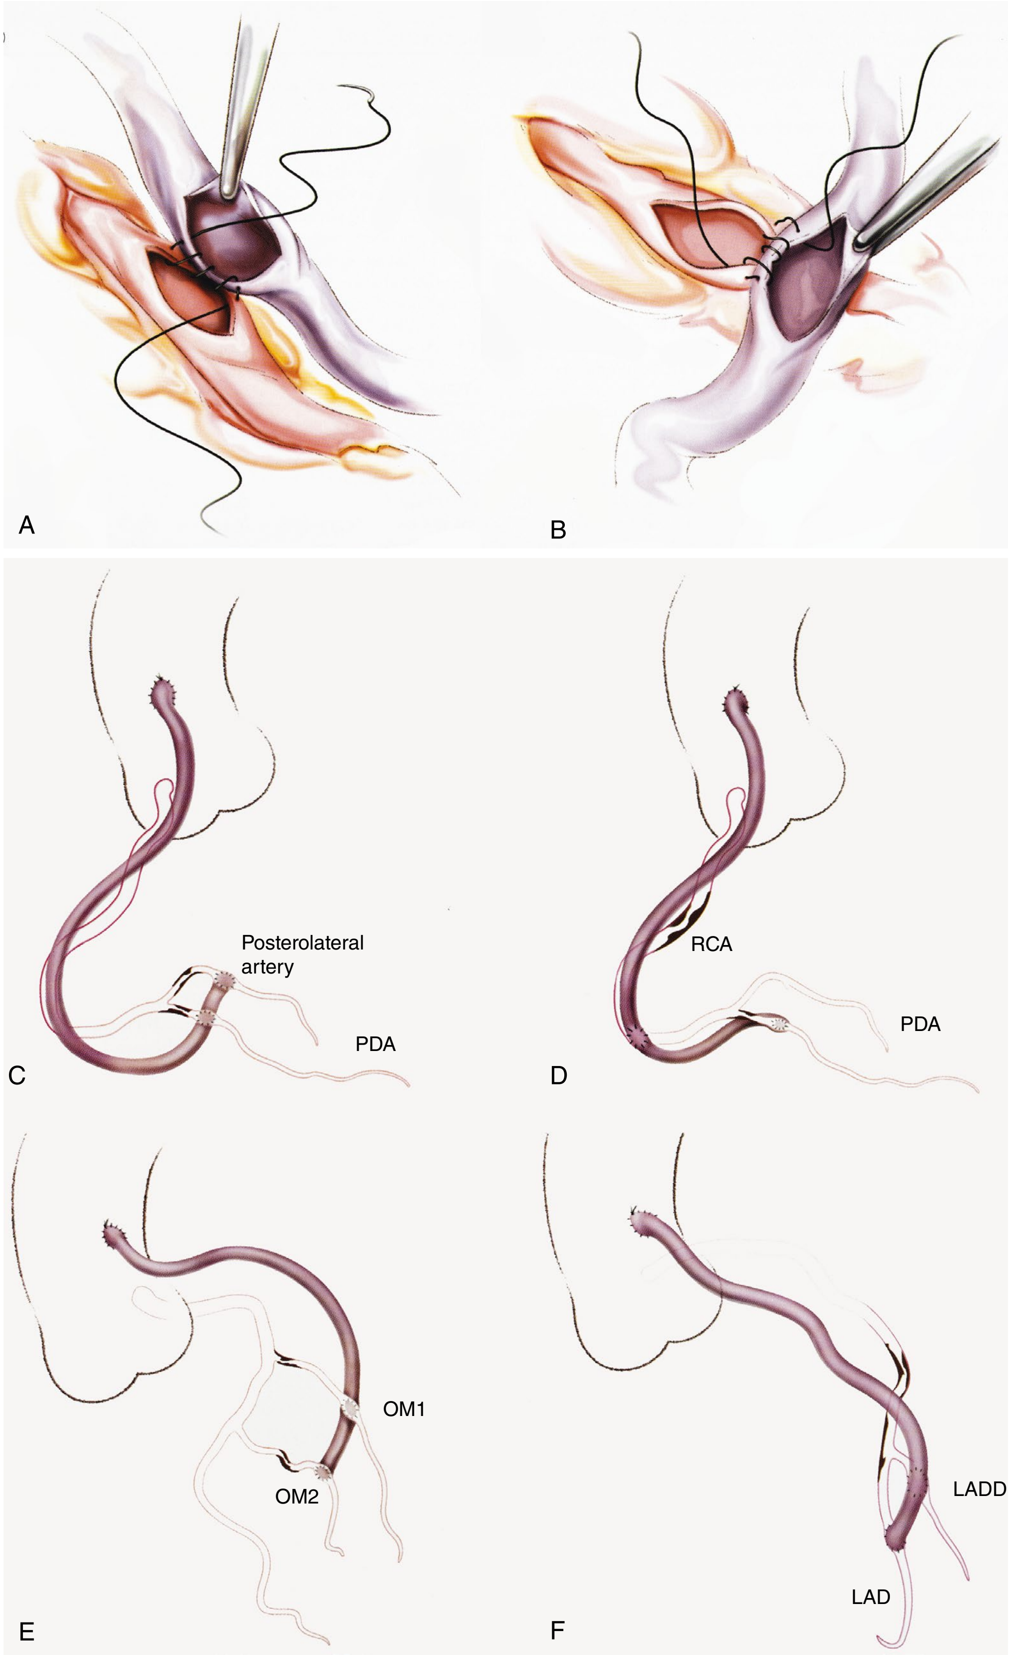

FIGURE 111.11 Distal coronary artery bypass grafting with side-to-side anastomosis for sequential grafting with a single conduit. (A) Linear parallel side-to-side anastomosis. (B) Diamond-shaped perpendicular side-to-side anastomosis. (C) Sequential anastomosis from aorta to posterior descending artery (perpendicular side to side) and the posterolateral artery (end to side). (D) Sequential anastomosis from aorta to right coronary artery (parallel side to side) and to the posterior descending artery (end to side). (E) Sequential anastomosis from aorta to first obtuse marginal artery (perpendicular side to side) and the second obtuse marginal (end to side). (F) Sequential anastomosis from aorta to diagonal artery (parallel side to side) and the LAD (end to side). *LAD,* Left anterior descending artery; *LADD,* left anterior descending diagonal artery; *OM1,* obtuse marginal 1; *OM2,* obtuse marginal 2; *PDA,* posterior descending artery; *RCA,* right coronary artery. trial of CABG,[87] this analysis found that TECAB was associated with similar mortality rates (perioperative mortality of 1.7% and 3.5% all-cause mortality in the trial). However, whereas the FREEDOM trial was a high-quality RCT, this systematic review was subject to potential selection bias.[87] Of note, there was no control group in the review, and most of the studies included were single-center and retrospective in nature with experienced surgeons. The theoretical benefit of reduced postoperative length of stay in robotically assisted TECAB has yet to be fully actualized. Overcoming the steep learning curve and integrating more robotic exposure during training may play an important role in optimizing outcomes in patients undergoing TECAB.

HYBRID CORONARY SURGERY

Hybrid coronary revascularization (HCR) is a combined surgical and percutaneous technique used in the treatment of multivessel CAD (MVCAD). This involves a surgical LIMA-to-LAD anastomosis (often performed minimally invasively) with PCI of the additional significantly stenosed coronary arteries. The order of events of the two procedures is variable and often raises issues of timing of initiation of DAPT. Various meta-analyses have been conducted to evaluate its effectiveness compared with CABG. Sardar et al. (2017) evaluated eight studies with 2245 patients (1 RCT and 7 OTs). End points included all-cause mortality, incidence of MI, stroke, repeat revascularization, need for postoperative transfusion, and hospital stay. Compared with the control group (CABG), patients with HCR experienced similar all-cause mortality (OR 0.84, 95% CI 0.38–1.88), MI (OR 0.72, 95% CI 0.31–1.64), stroke (OR 0.53, 95% CI 0.23–1.20), and repeat revascularization (OR 1.28, 95% CI 0.58–2.83). However, HCR patients were less likely to receive postoperative blood transfusion (OR, 0.29; 95% CI 0.14–0.59) and had shorter hospital length of stay (weighted difference –1.20; 95% CI –1.51 to –0.88 days).[148] A more recent meta-analysis of 18 studies (3 RCTs and 15 OTs) investigated the perioperative, short-term (30 days to 1 year), medium-term (1–5 years), and long-term (>5 years) outcomes of HCR versus CABG. Overall, the incidence of MACCE between HCR and CABG was similar in the perioperative period (OR 0.90, 95% CI 0.54–1.48, $p = 0.67$), short-term follow-up (OR 1.35, 95% CI 0.73–2.49, $p = 0.34$), medium-term period (OR 1.25, 95%, CI 0.53–2.97, $p = 0.61$), and long-term period (OR 0.93, 95% CI 0.61–1.41, $p = 0.72$). The rate of MI and mortality at all follow-up points was similar between groups. Of the seven studies that evaluated repeat revascularization, HCR was associated with significantly higher rates in the perioperative (OR 3.5, 95% CI 2.07–5.94, $p < 0.001$), short-term (OR 3.28, 95% CI 1.62–6.64, $p < 0.001$), and medium-term need for repeat revascularization (OR 2.84, 95% CI 1.64–4.92, $p < 0.001$). This difference was not observed during the long-term (>5 years) follow-up (OR 1.05, 95% CI 0.71–1.53, $p = 0.82$).[149] More randomized clinical trials comparing HCR to CABG are needed to fully explore the long-term outcomes of this novel and nuanced approach to surgical revascularization.

COMPLETENESS OF REVASCULARIZATION

In the management of patients with multivessel disease, the goal is to achieve CR of all significantly stenosed vessels (>70% for non–left main targets and >50% for the LMCA). Incomplete revascularization has been shown in retrospective studies and other trials to be associated with reduced long-term survival.[150–152] However, patient-specific factors and shared decision-making are critical when determining the ability to provide CR to all significantly stenosed target vessels.

In patients with STEMI, PCI of the culprit lesion is often the sole target treated during emergent revascularization.[21] Unfortunately, these patients often have other angiographically significant lesions, apart from the lesion precipitating the acute MI. Observational studies suggest that outcomes are less favorable when significantly stenosed epicardial vessels are left untreated. This correlation is further supported by the SYNTAX trial, which observed worse cardiovascular outcomes in patients receiving incomplete revascularization during CABG or PCI, despite the trial's aim for CR in all participants.[67,68]

The current ACC/AHA/SCAI Guideline on Coronary Artery Revascularization recommends staged PCI of significant noninfarct artery stenosis in selected hemodynamically stable patients with STEMI and noncomplex multivessel nonculprit disease (COR 1) and elective CABG in selected patients with STEMI and complex multivessel noninfarct disease after successful primary PCI (COR 2a).[21] Patients who receive incomplete revascularization often present with more complex comorbidities, such as advanced age, diabetes, renal failure, previous MI, reduced left ventricular function, and complex or prohibitive coronary anatomy. These factors can inherently influence the decision-making process and feasibility of achieving CR, thereby potentially affecting patient outcomes.[67,68,153]

TECHNICAL ASPECTS OF REOPERATIVE CORONARY ARTERY BYPASS GRAFTING

Surgical revascularization after a previous CABG presents several unique technical challenges that are complex and multifaceted. These difficulties stem from anatomic and physiologic changes, including scar tissue and adhesions around the heart and great vessels, which makes sternal reentry risky because any structure can be adherent to the posterior table of the sternum. Scar tissue and adhesions also make the identification of structures challenging, putting previously placed bypass grafts at risk. The LIMA is at significant risk of injury with redo sternotomy because of its course along or beneath the left side of the sternum. In addition, patients undergoing repeat revascularization often have a higher-risk profile, including advanced age, comorbidities, and a greater extent of CAD. Hence, these patients face greater risks with redo CABG, including increased rates of in-hospital death and stroke, compared with those undergoing PCI. As a result, PCI is generally favored over redo CABG for revascularization, particularly when a LIMA-to-LAD bypass is not planned or if a patent LIMA-LAD graft already exists.[21] Although some observational studies suggest that redo CABG might offer better long-term outcomes than PCI, these findings are inconsistent and not conclusively supported by high-quality RCTs. In sum, according to the 2021 ACC/AHA/SCAI Guideline on Coronary Artery Revascularization, in patients with previous CABG who require repeat revascularization, PCI may be preferable to CABG if they have a patent LIMA-LAD graft (Class 2a).[14] For those with previous CABG who suffer from refractory angina as a result of LAD disease despite GDMT, selecting CABG over PCI is advisable if an IMA can be used as a graft to the LAD (Class 2a).[21] Additionally, in cases of complex CAD after a prior CABG, choosing CABG over PCI may be a reasonable approach when an IMA graft to the LAD is possible (Class 2b).[21]

ADJUNCTS TO CORONARY ARTERY BYPASS GRAFTING

Various adjuncts play crucial roles in enhancing the safety, efficacy, and long-term success of CABG. These include pharmacologic agents, such as antiplatelet therapy to prevent graft thrombosis and statins for lipid control, which are essential in improving graft patency and reducing cardiovascular events postsurgery. Intraoperative placement of mechanical circulatory support devices, such as the IABP, can provide hemodynamic augmentation in high-risk patients. Additionally, technologic advances, such as endoscopic vessel harvesting and anastomotic devices, may offer certain advantages.[154]

Imaging strategies, including epiaortic ultrasonography (EAU), transesophageal echocardiography (TEE), and intraoperative graft flow assessment, are essential adjuncts to safe and effective CABG. Postoperative care, including strict glycemic control and rehabilitation programs, also plays a pivotal role in patient recovery and long-term well-being. These adjuncts, when effectively integrated into CABG procedures, significantly contribute to optimizing patient outcomes and improving the overall success of surgical coronary revascularization.[21,25]

Epiaortic Ultrasonography

EAU has become an increasingly important adjunct in CABG surgery, particularly in reducing the risk of perioperative stroke. It offers a more accurate assessment of the ascending aorta anatomy and atherosclerotic disease compared with traditional methods of palpation or TEE.[155–157] Given that microembolic and macroembolic strokes are often associated with aortic manipulation during surgery, the use of EAU to guide cannulation, decisions about aortic cross-clamping, and aortocoronary anastomosis placement is clinically valuable. When the ascending aorta is unsuitable for both cross-clamp and cardioplegia catheter placement, surgeons can employ the off-pump or on-pump beating technique.[155–158] This method becomes particularly relevant when the entire aortic surface precludes cannulation, necessitating alternative approaches. In such instances, a "no-touch" technique is advisable, wherein the femoral, innominate, or axillary artery is employed for arterial inflow during CPB. This approach is complemented by originating proximal anastomoses from one or both IMAs. This flexibility in cannulation strategies underscores the importance of adaptive surgical techniques in managing complex cardiac surgical cases. The European Multicenter Study on Coronary Artery Bypass Grafting (E-CABG) registry investigated the impact of EAU-guided aortic manipulation on outcomes after isolated CABG. The study included 673 patients out of 7241 (9.3%) who underwent intraoperative EAU. Overall, the rate of stroke in patients who had aortic manipulation without the use of EAU was 1.4% versus 0.6% in patients whose aortic manipulation was EAU guided.[157] In 660 propensity-matched pairs, there was a significant association between EAU-guided aortic manipulation and a reduced risk of stroke (0.6% vs. 2.6%, $p = 0.007$).[157] A systematic review and meta-analysis, incorporating this and other studies, further substantiated these findings.[159] The pooled data from these studies, which included 11,496 patients, of whom 3026 (25.7%) underwent intraoperative EAU, demonstrated a significantly lower rate of postoperative stroke in patients with EAU-guided aortic manipulation compared with those without (0.6% vs. 1.9%, RR 0.40, 95% CI 0.24–0.66). Therefore, the 2021 ACC/AHA/SCAI Guideline for Coronary Artery Revascularization includes a COR 2a recommendation for the routine use of EAU to assess for the presence, severity, and location of plaque in the ascending aorta during CABG to reduce embolic events.[21]

Transesophageal Echocardiography

Beyond the assessment of LVEF, TEE can help evaluate ventricular wall motion abnormalities, congenital and acquired heart defects (patent foramen ovale, tumors, etc.), and valvular pathologies that may affect the outcome of a planned CABG.[25] Together with the use of intraoperative transit time flow measurement, TEE assessment of ventricular wall motion can inform decisions regarding the need for intraoperative revision of bypass grafts.[160] TEE can also guide pharmacologic management and facilitate weaning from CPB by detecting intracardiac air and new wall motion abnormalities. The use of intraoperative TEE during CABG has been the subject of various studies, highlighting its impact on surgical decision-making and outcomes.[25,158–162]

A comprehensive retrospective analysis of more than 1.25 million planned CABG procedures across 1218 centers evaluated the impact of intraoperative TEE on clinical decision-making and postoperative mortality. The study found that intraoperative TEE was used in 53.9% of CABG cases and was associated with lower odds of postoperative mortality, particularly in higher-risk patients (adjusted OR 0.95, 95% CI 0.91–0.99, $p = 0.025$). Interestingly, the use of intraoperative TEE was associated with an increased likelihood of unplanned valve procedures during CABG (adjusted OR 4.98, 95% CI 3.98–6.22, $p < 0.0001$).[59] The 2021 ACC/AHA/SCAI Guideline for Coronary Artery Revascularization recognized the importance of using TEE for the real-time assessment of patients undergoing combined CABG and valvular procedures. However, the guideline notes that the use of TEE is less frequent in isolated CABG cases, but it clearly has a role in influencing surgical decisions as well as hemodynamic status assessment in CABG patients.[21,162]

Inotropes and Pharmacotherapy After Coronary Artery Bypass Grafting

The value of high-quality medical and critical care management of patients after CABG cannot be overstated. A myriad of pharmacotherapy is commonly prescribed for the pre-, intra-, and postoperative phases of care. Summarized in Table 111.5 are some of the key inotropes and other medications used as adjuncts in CABG.

Intraaortic Balloon Pump

The IABP plays a critical role in CABG surgery, particularly for high-risk patients. It operates by counterpulsation in synchrony with the cardiac cycle. During diastole, the IABP inflates, increasing coronary perfusion by raising diastolic pressure. Conversely, it deflates just before systole, reducing LV afterload and thereby enhancing cardiac output and reducing myocardial oxygen demand.

Importantly, IABP is strictly contraindicated in patients with conditions like aortic regurgitation and aortic dissection, and its use is relatively contraindicated in those with PVD or abdominal aortic aneurysm. A meta-analysis of randomized trials and prospective study designs assessed the outcomes of preemptive IABP use in high-risk CABG patients. The analysis included 1171 subjects from nine RCTs, revealing significantly lower mortality and MACCEs in patients receiving IABP compared with controls ($n = 594$ patients without preoperative IABP). Importantly, the rate of IABP-related complications was 5.6% (17/304), with limb ischemia and insertion site hematoma being the most common complications.[163]

COMPLICATIONS OF CORONARY ARTERY BYPASS SURGERY

The complications of CABG span multiple organ systems and emphasize the necessity of meticulous surgical technique and rigorous postoperative management. Cardiovascular complications such as myocardial stunning, tamponade, and air embolism highlight the importance of adequate myocardial protection, proper surgical techniques, and adequate hemostasis. Pulmonary and central nervous system adverse events underscore the need for preoperative assessments and careful monitoring, whereas renal and hematologic complications call for vigilant management to prevent negative outcomes. The prevention strategies emphasize the role of careful patient evaluation, precise surgical practice, and tailored postoperative care to mitigate these risks. These complications are summarized in Table 111.6.

CORONARY ARTERY BYPASS GRAFTING AND SPECIAL POPULATIONS OF PATIENTS

Females

The clinical presentation of ACS often differs between males and females. Females are more likely to present with atypical symptoms, such as nausea, vomiting, mid-epigastric discomfort, or sharp (atypical) chest pain. Several landmark trials have shown significant sex differences in the clinical presentation of ACS, including the Women's Ischemia Syndrome Evaluation (WISE) trial,[164] the Can Rapid Risk Stratification of Unstable Angina Patients (CRUSADE) trial,[165] the Variation in Recovery: Role of Gender on Outcomes of Young AMI Patients (VIRGO) trial,[166] and the International Survey of Acute Coronary Syndromes in Transitional Countries (ISACS-TC) trial.[167] For example, in the WISE study, females had a higher 30-day post-ACS mortality rate compared with males (9.6% vs. 5.3%, OR 1.91). Females also experienced more persistent chest pain and frequent hospitalizations, with lower well-being scores and higher daily activity limitations. These outcomes occurred despite females having lower SYNTAX scores. Remarkably, more than 50% of females with ACS symptoms showed no obstructive coronary disease during coronary angiography. The 2021 ACC/AHA/SCAI Guideline for Coronary Artery Revascularization recommends taking these factors into consideration when dealing with females presenting with symptoms suggestive of CAD.[21]

Pregnant Patients

Although the incidence of CAD and AMI in females of childbearing age is generally low, pregnancy has been associated with up to a fourfold increase in the risk of AMI compared with nonpregnant females.[166,168–172] The incidence of pregnancy-associated MI (PAMI) ranges from 2.8 to 8.1 AMI events per 100,000/deliveries, with a significant increase in risk for females over 35 and those with preexisting conditions such as hypertension, diabetes, or a history of smoking.[170,171] The case fatality rate for AMI in pregnancy is reported to be 5.1% to 37%. In addition to threatening the life of the mother, PAMI and other cardiovascular complications of pregnancy, including spontaneous coronary artery dissection (SCAD) and hypertension, pose a significant risk of fetal loss. Importantly, the prevalence of hypertensive disorders in pregnancy has been linked to future maternal cardiovascular risk.[168]

Managing pregnant females with CAD requires a multidisciplinary approach. Guidelines stress the importance of prepregnancy risk assessment and counseling.[21] For females with known CAD or at high risk, careful monitoring and management of risk factors are essential.[21,169,170] Therapeutic strategies should balance maternal and fetal safety while considering medication teratogenicity.

In cases of AMI, treatment protocols similar to those for nonpregnant populations are recommended, with adaptations for fetal safety.[169,170] Treatment should never be delayed in pregnant females presenting with STEMI because of radiation concerns. The standard revascularization goal of <90 minutes from first medical contact to device should be maintained, and PCI

TABLE 111.5 Commonly Used Pharmacotherapies in CABG Patients

DRUG (GENERIC AND TRADE NAMES)	MECHANISM OF ACTION/ALERTS	INDICATIONS	INTRAVENOUS DOSAGE
Dopamine (Intropin)	Stimulates β_1-adrenergic and dopaminergic receptors; at high doses, α-adrenergic effects (arterial vasoconstriction). Known to increase myocardial O_2 consumption. Worse outcomes in shock compared with epinephrine.	Low cardiac output	1–25 mcg/kg/min
Dobutamine (Dobutrex)	Selective β_1-adrenergic agonist with mild β_2 and α_1 effects (inodilator). Can increase myocardial O_2 consumption.	Cardiac support in low-cardiac-output states	2.5–25 mcg/kg/min
Epinephrine (Adrenalin)	α- and β-adrenergic agonist	Severe hypotension, cardiac arrest	0.01–0.25 mcg/kg/min
Norepinephrine (Levophed)	Potent α-adrenergic agonist with mild β-adrenergic effects	Hypotension not responsive to other inotropes	0.01–0.4 mcg/kg/min
Phenylephrine Neo-synephrine)	Catecholamine, pure α-agonist	Severe vasoplegia, hemodynamically significant LVOT obstruction	0.1–4 mcg/kg/min
Isoproterenol (Isuprel)	Pure β-agonist; predominantly increases heart rate, with an associated increase in contractility	Symptomatic bradycardia, including prevention of bradycardic-dependent arrhythmias (torsades de pointes)	0.02–0.2 mcg/kg/min
Milrinone (Primacor)	Phosphodiesterase-3 inhibitor; increases cAMP, leading to vasodilation and inotropy	Heart failure, low-cardiac-output syndrome	0.125–0.75 mcg/kg/min
Vasopressin (Pitressin)	Vasopressin V1 receptor agonist; increases vascular smooth muscle contraction	Vasodilatory shock, especially septic shock	0.01–0.04 units/min
Nitroglycerin	Nitric oxide donor, causing vasodilation	Myocardial ischemia, hypertension, heart failure	5–400 kg/min
Nitroprusside (Nipride)	Nitric oxide donor, strong vasodilator	Hypertensive urgency or emergency, critical blood pressure control in acute aortic dissection	0.1–10 mcg/kg/min
Amiodarone	Class III antiarrhythmic prolongs cardiac action potential. Known to potentiate warfarin in postoperative period and synergistic with other QT-prolonging medications. Beware of torsades de pointes.	Atrial and ventricular arrhythmias	Loading: 150 mg over 10 min Maintenance: 1 mg/min for 6 hours, then 0.5 mg/min × 18 hours
Lidocaine	Class Ib antiarrhythmic; blocks sodium channels	Ventricular arrhythmias	Bolus: 1–1.5 mg/kg Infusion: 1–4 mg/min
β-Blockers (e.g., Metoprolol tartrate)	Blocks β-adrenergic receptors, reducing heart rate and contractility	Tachyarrhythmias, especially atrial fibrillation rate control	Varies based on drug, e.g., Metoprolol: 5 mg every 5 minutes up to 3 doses
Furosemide	Loop diuretic; inhibits Na-K-2Cl cotransporter in the loop of Henle	Fluid overload, acute pulmonary edema; most administered diuretic after CABG	10–40 mg IV, 20–40 mg PO 1–2 times daily; may be repeated or increased as needed

Note: It is prudent to use clinical judgment in evaluating the appropriateness and dosing of these medications for individual patients after CABG.

CABG, Coronary artery bypass graft; *cAMP,* CYCLIC adenosine monophosphate; *LVOT,* left ventricular outflow tract; *O_2,* oxygen; *Na-K-2Cl,* sodium-potassium-chloride cotransporter; *PO,* per os (by mouth).

can be performed once SCAD has been ruled out (COR 2a).[21] Fibrinolytic therapy should only be employed if PCI is not suitable.[169] Furthermore, in pregnant females with NSTE-ACS, an invasive strategy may be employed if medical therapy proves ineffective (COR 2a).[21] Regional anesthesia might be preferred over general anesthesia. Careful positioning is vital to avoid aortocaval compression. The left lateral decubitus position is often recommended. Close monitoring of hemodynamic status is crucial, considering the increased cardiac output and altered vascular resistance in pregnancy. Postoperative care should include careful monitoring for signs of cardiac decompensation, given the increased cardiovascular demands during the postpartum period.[169,171,172]

CABG in pregnant patients is complex, with specific indications for CABG involving hemodynamic instability or ongoing ischemia despite conservative treatment (COR 2a).[21,173] Most SCAD patients improve with conservative management, including aspirin and β-blockers like labetalol, recommended because of its safety in pregnancy. Clopidogrel's use requires careful consideration due to limited safety data in pregnancy. In SCAD cases requiring intervention, CABG has been performed, noting varied fetal outcomes. Given SCAD's high recurrence risk with

TABLE 111.6 Summary of Common Complications of CABG, Associated Risks and Prevention

ORGAN SYSTEM	CLINICAL EXAMPLES	ASSOCIATED FEATURES	RISK FACTORS	PREVENTION
Cardiovascular	Myocardial stunning	Postischemic contractile dysfunction seen in 10%–70% of patients. Associated with up to 17% mortality in some series.[121]	Fluid overload and edema, inadequate myocardial protection during aortic cross clamp, effect of global ischemia imposed upon heart during cardioplegia arrest	Ensure adequate myocardial protection during arrest (frequent and complete cardioplegia administration); minimize CPB time.[121]
	Air embolism	Rapid cardiovascular collapse	Improper cannulation or de-airing techniques; use of central venous catheters; structural heart defects (PFO)	Follow the best surgical practices. For air in the aortic cannula, promptly identify air embolism, and stop the pump immediately. Clamp both arterial and venous lines, place patient in Trendelenburg position, ventilate with 100% O_2, and remove aortic cannula to de-air aorta. Place arterial cannula in SVC for RCP, clamping SVC proximally. Manually compress the heart and carotids and reinitiate CPB at higher pressures when de-aired.[124]
	Injuries to vessels and other heart structures (e.g., coronary sinus perforation, left ventricular perforation from venting, sinus node injuries)	Significant hemorrhage and arrhythmias may result from inadvertent coronary sinus perforation during retrograde catheter placement. LV may be perforated from LV vent placement. Injury to conduction system by sutures for tricuspid, mitral, or aortic valve procedures.	Emergency or urgent cases (crashing onto bypass); purse-string sutures under tension or excessive retraction; prolonged CPB time, poor preoperative ventricular function[121]	Good exposure for cannula placement and verification before use; epiaortic US for cannula placement[121]
	Postoperative arrhythmias	SVTs, AF, VT, and heart block	History of arrhythmias (e.g., AF), electrolyte imbalance, surgical trauma and manipulation, intracoronary air embolism, and ischemic injury	Minimize surgical trauma and manipulation; strict adherence to electrolyte monitoring and replacement. β-blockade.
	Graft failure Coronary spasm	Decreased graft flow on imaging, new wall motion abnormalities on echo, or new evidence of myocardial ischemia	Poor target artery quality, small graft or target artery diameter, smoking, DM, HLD	Choice of graft (arterial grafts like the LITA have better long-term patency compared with vein grafts) and management of risk, such as HLD, HTN, DM
	Bleeding Tamponade Delayed tamponade	Pericardial effusion on echo; labs may show dropping hemoglobin level; acute hypotension, muffled heart sounds, JVD	Use of anticoagulants, surgical technique, preexisting coagulopathies	Meticulous technique, careful postoperative anticoagulation management, close monitoring for signs of bleeding
Pulmonary (most injured organ)	Atelectasis Pleural effusion Pulmonary edema Pneumonia	Difficulty liberating from the ventilator, early postoperative fever, poor oxygenation status	Preexisting lung disease (COPD), advanced age, prolonged ischemic or CPB time (>120 minutes), preferential ventilation of nondependent lung segments; phrenic nerve injury[124]	Early postoperative detection and respiratory physiotherapy; early ambulation; ventilation with PEEP
	Acute respiratory distress syndrome	Rapid-onset hypoxemia with significant reduction in Pao_2/Fio_2 ratio <200 mm Hg; diffuse pulmonary infiltrates on chest radiograph	Poor preoperative nutritional status, prolonged ischemia or CPB time, diabetes and postoperative APACHE II score, emergency surgery[122,123]	Some RCTs and other observational studies have yielded conflicting results about low-frequency lung-protective mechanical ventilation during CABG.[126]
	Respiratory failure Prolonged ventilation	Pulmonary edema, atelectasis, pneumonia	Chronic lung disease, smoking history, obesity, lengthy surgery, advanced age	Preoperative pulmonary evaluation and optimization, smoking cessation, early mobilization, respiratory therapy pre- and postoperatively

TABLE 111.6 Summary of Common Complications of CABG, Associated Risks and Prevention—cont'd

ORGAN SYSTEM	CLINICAL EXAMPLES	ASSOCIATED FEATURES	RISK FACTORS	PREVENTION
Central nervous system	Acute delirium Encephalopathy Stroke Memory deficits	Deficits may be subtle and difficult to quantify and categorize in the acute setting.	Aortic surgery and surgery requiring deep hypothermic circulatory arrest Prolonged regional or global hypoperfusion, microembolic phenomenon (gas, lipid, atheroma, bone marrow, glove powder, blood cells or fibrin, PVC tubing particles) or hemorrhage[124]	Address carotid disease before CABG; limit total ischemia time; avoid bypass manipulation and limiting drug administration or blood sample acquisition through the CPB circuit; no-touch technique for calcific aorta; judicious de-airing technique.[121]
Endocrine	Adrenergic overstimulation Stress-induced hyperglycemia Postoperative insulin resistance	Postoperative hyperglycemia that may be require insulin administration; nonthyroidal illness syndrome (low T3, low or normal T4, normal or slightly elevated TSH)[124]	Preexisting endocrine disorders (diabetes, thyroid disease), obesity, chronic kidney disease, history of corticosteroid use, prolonged CPB time, low-cardiac-output syndrome	Preoperative assessment, regular monitoring, and early consultation with endocrinologist
Renal complications	AKI (elevated creatinine and BUN) Progression to CKD or ESRD	AKI is associated with twentyfold increase in mortality or morbidity[121]	Preexisting kidney disease, hypertension, advanced age, DM, heart failure, use of IABP, nephrotoxic medications, obesity, emergency surgery	Maintain acceptable cardiac index and MAP, optimal glucose control, perioperative fluid management and minimize the use of nephrotoxic agents.
Hematologic complications	Coagulopathy Hemorrhage Anemia	Prolonged bleeding (e.g., CT drainage >200–300 mL/h) for first 1–3 hours postoperatively or sustained high output (>100–150 mL/h × 3–6 hours, or >1–1.5 L within 24 hours) or continued transfusion requirement	Intraoperative and postoperative hypothermia, inadequate hemostasis before sternal closure, CKD, preoperative use of anticoagulants or antiplatelets, massive transfusion, repeat CABG, emergency surgery, advanced age, liver disease, and inflammation/sepsis	Preoperative medication review, meticulous surgical technique, careful management of CPB and temperature
Immuno-allergic complications	Whole body inflammation cascade associated with CPB involves anaphylatoxins; cytokines TNF-α, IL-6, IL-8, and IL-10; endotoxins; and kallikrein-bradykinin reactants[124]	Increased vascular permeability, platelet aggregation. and SIRS varies by magnitude and has been shown to influence clinical outcomes after CPB.		
	Heparin-induced thrombocytopenia	IgG antibodies against complexes of heparin and PF4 Leads to thrombocytopenia and thrombosis	Previous exposure to UFH, prolonged or high-dose heparin exposure, females	Early recognition, minimizing heparin exposure, use of nonheparin anticoagulants or factor Xa inhibitors in patients with history of HIT, monitoring platelet count
Infection	Superficial wound infection Deep sternal wound infection Mediastinitis	Fever, erythema, purulence from wound site, and instability of the sternal wound	Obesity, smoking, DM, use of BIMA, prolonged ICU stay	Preincisional antibiotics, meticulous glucose control, smoking cessation
Gastrointestinal	Bowel ischemia Gastritis Hepatic dysfunction	Abdominal pain, nausea, gastrointestinal bleeding, ileus	Low cardiac output, prior gastrointestinal issues, medication side effects	Adequate hydration, early mobilization, monitoring and managing cardiac output and medication effects

AF, Atrial fibrillation; *AKI,* acute kidney injury; *APACHE,* acute physiology and chronic health evaluation; *BIMA,* bilateral internal mammary artery; *BUN,* blood urea nitrogen; *CABG,* coronary artery bypass graft; *CKD,* chronic kidney disease; *COPD,* chronic obstructive pulmonary disease; *CPB,* cardiopulmonary bypass; *CT,* computed tomography; *DM,* diabetes mellitus; *ESRD,* end-stage renal disease; *HIT,* heparin-induced thrombocytopenia; *HLD,* hyperlipidemia; *HTN,* hypertension; *IABP,* intraaortic balloon pump;, *ICU,* intensive care unit; *IgG,* immunoglobulin G; *IL,* interleukin; *JVD,* jugular venous distention; *LITA,* left internal thoracic artery; *LV,* left ventricle; *MAP,* mean arterial pressure; *PEEP,* positive end-expiratory pressure; *PF4,* platelet factor 4; *PFO,* patent foramen ovale; *PVC,* polyvinyl chloride; *RCP,* retrograde cerebral perfusion; *RCT,* randomized controlled trial; *SIRS,* systemic inflammatory response; *SVC,* superior vena cava; *SVT,* supraventricular tachycardia; *TNF-α,* tumor necrosis factor alpha; *TSH,* thyroid stimulating hormone; *UFH,* unfractionated heparin; *US,* ultrasonography; *VT,* ventricular tachycardia.

Data from Lawton JS and Gay WA. Complications of Extracorporeal Circulation in Complications in Surgery, 2nd ed, Lippincott, Williams,& Wilkins; Philadelphia; 2011: 290-297.

subsequent pregnancies, there is an ethical consideration regarding future pregnancies.[173] In summary, CAD and related cardiovascular diseases in pregnancy, although rare, require vigilant management and an understanding of the unique physiologic changes during pregnancy. Multidisciplinary care and adherence to guidelines are key in optimizing outcomes for both mother and fetus.

Patients With Diabetes

CAD is notably more prevalent in patients with diabetes and is associated with a tendency toward multivessel disease and an elevated risk of postoperative complications.[72,86,87] The pathophysiology of CAD in diabetic patients is complex and multifaceted. Hyperglycemia induces endothelial dysfunction, whereas dyslipidemia and chronic inflammation contribute to accelerated plaque formation and vascular complications. The management of CAD in diabetes involves comprehensive strategies, including aggressive control of blood glucose and lipid levels, hypertension management, lifestyle modifications, and pharmacotherapy to reduce cardiovascular risk factors.[21]

CABG and PCI are the primary revascularization techniques for CAD. Recent studies and guidelines favor CABG for diabetic patients with multivessel CAD because of its superior outcomes of mortality reduction and lower incidence of major cardiac events.[21,86,87] Research indicates that patient sex may influence outcomes in those with diabetes undergoing revascularization. Females with diabetes undergoing CABG may experience different long-term outcomes compared with their male counterparts, highlighting the need for sex-specific considerations in treatment planning. Postoperative complications, such as renal injury, prolonged intensive care unit (ICU) stay, and increased revascularization rates, are more common in diabetic patients. These challenges necessitate careful perioperative management, with a focus on glycemic control and cardiac function monitoring.[87]

In summary, diabetic patients with CAD require an integrated, multidisciplinary approach for optimal outcomes. Although CABG is generally favored for its long-term benefits in diabetic patients with complex multivessel disease (COR 1), as noted previously, individual patient characteristics, including sex and specific comorbidities, should guide treatment decisions.[21,174]

Patients With Renal Disease

Heart surgeons must confront the formidable challenge of managing CAD patients with concurrent CKD. In fact, patients with CKD have a notably higher prevalence of CAD due to shared risk factors, including hypertension, diabetes, and dyslipidemia.[175,176] In addition to the traditional risk factors for CAD, uremia and various microvascular changes in CKD patients exacerbate atherosclerosis by promoting inflammation, oxidative stress, vascular calcification, and endothelial dysfunction. Impaired renal function leads to fluid overload and hypertension, increasing cardiac workload and risk of coronary ischemia.[177]

A landmark study conducted by Alan S. Go et al. (2004) assessed the impact of varying degrees of kidney dysfunction on death, cardiovascular events, and hospitalization risks. The study followed over 1.1 million adults, finding a graded increase in risk of adverse outcomes with decreasing glomerular filtration rate (GFR). Key findings included a substantial rise in death risk and cardiovascular events for patients with a GFR below 60 mL/min/1.73 m^2, with risks sharply intensifying below 45 mL/min/1.73 m^2. The study underlined the clinical and public health importance of chronic renal insufficiency, especially in the context of cardiovascular disease.[178] Diagnosing CAD in CKD patients is complicated because of the reduced sensitivity and specificity of traditional tools. Coronary angiography and revascularization, despite their risks, remain the gold standards for diagnosing and treating diabetic patients with STEMI, with caution regarding contrast-induced nephropathy (CIN; COR 1).[21,174] Furthermore, in high-risk CKD patients with NSTE-ACS, coronary angiography and revascularization are reasonable (COR 2a).[21]

CAD in CKD involves balancing renal function preservation and cardiac event prevention. Pharmacotherapy often requires dosing adjustments in CKD. The 2021 ACC/AHA/SCAI Guideline for Coronary Artery Revascularization and the 2023 AHA/ACC/ACCP/ASPC/NLA/PCNA Guideline for the Management of Patients With Chronic Coronary Disease consolidate the latest evidence on managing patients with CAD and CKD and provide a patient-centered approach, integrating new therapeutic advances and emphasizing the importance of managing complex cases where coronary disease intersects with renal impairment. They highlight the necessity of a holistic approach in managing CCD, considering factors like renal function that significantly affect treatment outcomes and patient quality of life. Between PCI and CABG, CABG is often preferred in severe CKD for its long-term benefits despite initial risks.[21,174]

The 2021 ACC/AHA/SCAI Guideline for Coronary Artery Revascularization recommends renoprotective strategies, such as minimizing nephrotoxic agents and contract media exposure, in patients with CKD presenting with CAD (COR 1). However, coronary angiography and revascularization remain crucial in these patients. Hydration and use of N-acetylcysteine (NAC) may help prevent CIN, but some studies have presented conflicting benefits of NAC.[179,180] Furthermore, in dialysis patients, timing of surgery relative to dialysis sessions is important because preoperative dialysis may help remove excess fluid and uremic toxins. As such, a multidisciplinary approach involving cardiologists, nephrologists, cardiac surgeons, and intensivists is necessary because of the complex interplay between cardiac and renal function.[21,174]

Obese Patients

Obesity is strongly associated with the prognosis of atherosclerosis, a hallmark of CAD. In fact, over 80% of patients with coronary heart disease are overweight (BMI >25) or obese (BMI >30).[181] Adipose tissue, beyond its role in lipid storage, secretes cytokines known as *adipokines,* influencing whole body metabolism, inflammation, and endocrine functions. Adipokines play vital roles in the development, progression, and regression of atherosclerosis.[182]

Diagnosing CAD in obese patients is challenging. The sensitivity and specificity of traditional noninvasive tests, such as treadmill stress testing, are reduced in this population. Obesity can also limit the diagnostic utility of imaging modalities because of technical limitations and reduced image quality. Consequently, clinicians often need to rely on more advanced diagnostic techniques, such as CCTA or invasive coronary angiography, for accurate assessment.[21,174]

In addition to the technical challenges of performing CABG in obese patients, these patients often have a higher burden of comorbidities, such as diabetes and hypertension, which complicates perioperative management. The presence of thickened myocardium and epicardial fat can make surgical access and grafting more difficult. Additionally, obese patients have an increased risk of wound infection and slower recovery after surgery.[181,183]

The clinical outcomes of CABG in obese patients are nuanced. Although obesity is associated with an increased risk of perioperative complications, studies have shown a paradoxical survival benefit in obese patients after CABG, known as the *obesity paradox*.[183–185] However, this does not negate the increased risk of postoperative complications such as wound infections, deep vein thrombosis, and prolonged hospital stay.[181,186] A study by Pirlet et al. (2020) included a propensity-matched cohort of 116 patients with prior bariatric surgery (49 of whom underwent CABG and 67 PCI) compared with a PCI/CABG control group (without history of bariatric surgery). With a median follow-up of 8.9 years, key findings included a lower rate of MACCEs in the bariatric surgery group, driven by a reduction in noncardiac mortality. However, there were no significant differences in all-cause death, cardiac death, MI, stroke, or repeat myocardial revascularization rates. The study concluded that although bariatric surgery may reduce MACCE in obese CAD patients, this effect seems unrelated to direct cardiovascular outcomes.[186]

In conclusion, the management of CAD and the conduct of CABG in obese patients require special consideration because of the unique challenges in diagnosis, technical difficulties in surgery, and the complex interplay of clinical outcomes post-CABG. This emphasizes the need for a tailored approach to treating obese patients with CAD.

Patients 70 Years and Older

By 2030, one in six people will be over 60, and the number of octogenarians is expected to triple by 2050.[187,188] CAD, especially ACS, is a significant cause of death in this group, accounting for a substantial portion of hospitalizations and deaths related to ACS.[167] The aging population faces unique challenges in CAD diagnosis, management, and outcomes because of physiologic changes and comorbidities. In older adults, the pathophysiology of CAD is often compounded by age-related vascular changes, such as increased arterial stiffness, endothelial dysfunction, and a heightened inflammatory state. These factors exacerbate atherosclerotic processes, making older patients more susceptible to ischemic events.[21,174]

Older adults often present with atypical symptoms or may be asymptomatic, complicating ACS diagnosis. Traditional diagnostic tools such as ECG and biomarkers may yield nonspecific results due to age-related changes and comorbid conditions. Hence, a comprehensive approach, including detailed history, physical examination, and judicious use of diagnostic tests, is essential.[21,174]

A review by Chang et al. (2017) involved an individual patient-level meta-analysis, drawing data from the Bypass Surgery Versus Everolimus-Eluting Stent Implantation for Multivessel Coronary Artery Disease (BEST), Premedication for Crossover From Coronary Angioplasty to Surgery (PRECOMBAT), and SYNTAX trials, encompassing a total of 1079 adults aged 70 to 89 years. The primary outcomes were composite of death from any cause, MI, stroke, or repeat revascularization. Over a median follow-up of 4.9 years, the primary composite outcome of all-cause mortality, MI, stroke, or repeat revascularization occurred in 26% of patients in the CABG group and 34% in the PCI group. This indicated a lower risk associated with CABG (HR = 0.75, 95% CI 0.60–0.94, $p = 0.012$).[189] CABG was associated with fewer MIs and repeat revascularizations but did not significantly affect all-cause mortality or stroke rates. The study found that older adults aged 70 to 89 years with left main or multivessel CAD benefit more from CABG, especially those with high anatomic risk scores indicated by high SYNTAX scores. The study concluded that in older adults with severe left main or multivessel CAD, CABG may offer a more favorable outcome in reducing MACCEs, particularly in those with more complex disease. However, the study acknowledges limitations due to its nature as a subgroup analysis of randomized clinical trials; potential biases in patient selection; and the inability to include variables, such as frailty, cognitive dysfunction, and multiple comorbidities, that can influence outcomes.[183]

CABG presents unique challenges in the elderly. Age-related anatomic and physiologic changes, such as vessel calcification and reduced organ reserve, increase surgical complexity and risks. The presence of comorbidities such as diabetes, hypertension, and CKD further complicates the procedure, requiring careful preoperative assessment and tailored surgical techniques. Therefore, the ACC/AHA/SCAI Guideline for Coronary Artery Revascularization supports a comprehensive approach to CABG in older patients, incorporating considerations of the patient's preferences, life expectancy, and cognitive function (COR 1).[21]

Patients With Prior History of Coronary Artery Bypass Grafting

Patients undergoing CABG after a previous CABG procedure face distinct challenges and outcomes. Bourassa et al. (2002) demonstrated higher rates of death, MI, and need for revascularization in patients with prior CABG undergoing repeat surgical revascularization.[190] Although they exhibit poorer short-term outcomes, the observed differences may be related to confounding patient-specific comorbidities.[190] Notably, when PCI is performed on native vessels of patients with prior CABG, the adjusted clinical outcomes are similar to those in patients without prior CABG.[184] Interestingly, other studies have found that previous isolated CABG does not independently predict adverse outcomes in patients requiring proximal aortic or arch surgery.[191]

Based on various studies, the 2021 ACC/AHA/SCAI Guideline recommends, as noted previously, PCI over CABG for patients with prior CABG and a patent LIMA to the LAD (COR 2a). In cases of refractory angina despite maximal GDMT, CABG is advised over PCI if the LAD is the culprit lesion and an IMA is available for grafting (COR 2a). CABG is also considered in patients with complex CAD after CABG when an IMA can be used as a conduit (COR 2b).[21]

Revascularization Before Noncardiac Surgery

In 2006, the Coronary Artery Revascularization Prophylaxis (CARP) trial showed no survival benefits with preoperative coronary revascularization before elective vascular surgery in patients with concomitant ischemic CAD.[191] A follow-up study by Garcia et al. (2008) evaluated the impact of prophylactic coronary revascularization on long-term survival in patients with multivessel CAD undergoing elective vascular surgery. The study involved 1048 patients who underwent coronary angiography before vascular surgery as part of the CARP trial. It found that preoperative revascularization improved survival in patients with LMCA stenosis but not in those with either two-vessel or three-vessel disease. The study concluded that unprotected LMCA disease, present in 4.6% of the patients, was the only subset showing benefit from preoperative coronary artery revascularization.[192] Based on these and other studies, routine coronary revascularization in patients with non–left main or noncomplex CAD in preparation for another noncardiac surgery is not recommended (COR 3, no benefit).[21,174]

Patients Undergoing Other Cardiac Surgeries

Adding CABG to other cardiac procedures for patients with CAD should only be considered after important clinical factors have been thoroughly evaluated. These deliberations extend beyond patient comorbidities and include the technical aspects and feasibility of CABG, the degree of myocardial compromise, and conduit availability. Furthermore, the 2021 ACC/AHA/SCAI Guideline for Coronary Artery Revascularization recommends considering the patient's LVEF and the potential harm that extra CPB time necessary to add CABG may contribute to the procedure. As such, in patients with significant CAD who are undergoing valvular or aortic surgery, there is a COR 1 recommendation to add CABG to reduce MACEs. On the other hand, in patients with intermediate CAD, it may be reasonable to include CABG (COR 2a).[21,174] It is noteworthy to mention that age ≥85 years is an additional risk factor for worse clinical outcomes in patients undergoing concomitant CABG and other cardiac surgeries.[193]

Patients With Previous Heart Transplant

Cardiac allograft vasculopathy (CAV), a condition marked by extensive intimal hyperplasia, significantly contributes to the incidence of AMI and mortality after the first year of heart transplantation.[194] This condition poses a substantial challenge for cardiac surgeons. Current therapeutic options for CAV are notably limited. Although retransplantation remains the definitive treatment, obstacles such as the shortage of donor hearts and less favorable outcomes compared with the initial transplantation significantly impede its viability. For localized manifestations of CAV, the ACC/AHA/SCAI Guideline for Coronary Artery Revascularization offers a COR 2a recommendation for PCI as reasonable in patients with severe, proximal, discrete coronary lesions (and largely as a palliative measure), noting that stent implantation during PCI is associated with lower rates of perioperative and intermediate-term mortality compared with balloon angioplasty.[21,174]

Patients Pre– or Post–Lung Transplantation

CAD is often a comorbidity in candidates for lung transplantation. Studies have suggested that the presence of CAD at the time of lung transplantation does not meaningfully affect retransplant-free survival. However, greater technical complexity is noted in patients who underwent CABG before lung transplantation.[195] Notably, the STS recognizes a history of CABG as a relative contraindication for lung transplantation because of the observed increased risk of bleeding and death in these patients.[196] However, some series and observational studies have shown that this purported risk may not exist in patients receiving a single as opposed to double lung transplant.[197] Furthermore, the safety and feasibility of performing CABG at the time of lung transplantation have been widely reported.[198]

CABG post–lung transplantation presents a spectrum of technical challenges because of the presumed need for complex redo sternotomy and the dearth of evidence in the literature for best clinical practices. A PubMed, Semantic Scholar, and Google Scholar search on this topic yielded a brief abstract of a single case report by Harrison et al. (1997) for which there is no manuscript available electronically.[199] One case report by Larson et al. (2023) described a patient with ACS 15 years after concomitant CABG and bilateral lung transplant (BOLT) who underwent redo sternotomy for redo CABG that was complicated by dense mediastinal and pleural adhesions and had an acceptable recovery.[200]

Given that concomitant CABG and lung transplantation have become increasingly common with improvement in posttransplant immunosuppression and survival, the need for coronary re-revascularization in this patient population is expected to rise. As such, it is imperative for society guidelines to include recommendations and best practices for these unique patients.

Patients With Coronary Artery Aneurysm

A coronary artery is said to be aneurysmal when there is a minimum of 1.3 to 2 times luminal dilatation compared with an adjacent, normal arterial segment.[201] Coronary artery aneurysms and fistulae can be rare complications of coronary angiography but can also result from Kawasaki disease and Takayasu arteritis, with a reported estimated incidence of 0.02% to 0.2%.[202] Although most patients are asymptomatic, a number of complications can result, including vessel thrombosis, ischemia, fistula formation, and rupture. Several treatment strategies have been suggested in case reports, including stent placement, Amplatzer device deployment, and surgical bypass or exclusion of the aneurysmal segment; however, there are insufficient data to recommend one treatment over another.[202]

Patients With Anomalous Aortic Origin of a Coronary Artery

Anomalous origin of coronary artery (AAOCA) is among the congenital heart defects that may result in sudden cardiac death in individuals less than 35 years of age.[203]

Based on autopsy results, most patients die in association with periods of physical exertion such as exercise. There is a COR 1 recommendation from the 2018 AHA/ACC Guideline for the Management of Adults With Congenital Heart Disease to use coronary angiography, CT, or functional CMR imaging for diagnosis.[203] Management is complex and includes an assessment of the risk of ischemia and sudden death and the risk of surgical intervention. Surgical treatments range from unroofing to complex patch repair and may include CABG. Recommendations are summarized in the 2018 AHA/ACC Guideline for the Management of Adults With Congenital Heart Disease.[203]

Patients With Myocardial Bridging

Myocardial bridging is another congenital anomaly where myocardial tissue either completely or partially entraps a section of a coronary artery, potentially causing serious cardiac complications such as ischemia, arrhythmia, and sudden death.[21,204] Assessment is made by invasive methods (IVUS and angiography) and noninvasive techniques (Doppler ultrasound, multislice CT, and MRI). If a patient with myocardial bridging presents with ischemia, a baseline FFR may be obtained, followed by repeat FFR after dobutamine provocation. Surgery is reserved for patients with severe myocardial ischemia. There are currently no comprehensive society guidelines for the evaluation and management of CAD in patients with myocardial bridging.[204]

POSTOPERATIVE MANAGEMENT AND DISCHARGE FROM THE INTENSIVE CARE UNIT

CABG patients are admitted to the cardiovascular surgical ICU immediately after surgery. A detailed handoff should be provided by the surgical and anesthesia teams to the provider and nursing teams, followed by performance of a prompt physical exam. Bedside imaging (CXR) is obtained to verify the correct placement of the endotracheal tube, pulmonary artery catheters (if present), chest tube(s), central lines, and any mechanical circulatory devices (e.g., IABP). Special care is taken to identify any pneumothorax, pulmonary edema, hemothorax, or effusions that might be present. Baseline arterial blood gas (ABG) and a complete set of labs are obtained.[5] The ventilator (in patients who remain intubated) is adjusted based on ABG results, avoiding high positive end-expiratory pressure, especially in hemodynamically tenuous patients, as part of a lung-protective ventilation strategy (LPS).[205] Electrolytes are judiciously monitored and repleted as necessary.[5]

The immediate postoperative period after CABG should focus on stabilizing the patient's hemodynamics (cardiac index of >2.2 L/min/m^2, adequate mean arterial pressure of 60–80 mm Hg, sinus rhythm of 60–100 beats/min) by ensuring proper intravascular volume (preload), normalizing peripheral vascular resistance (PVR), and treating any identified arrhythmias. This often involves administering fluids, blood products, inotropes, or calcium to modulate vascular tone.[5,206] Maintaining a core body temperature above 36.5°C has also been associated with better clinical outcomes, including in-hospital mortality.[207]

Close monitoring of neurologic status and effective pain control are crucial. The use of nonopioid drugs (e.g., acetaminophen, ketamine, dexmedetomidine) and regional analgesia (e.g., truncal nerve blocks), especially when implemented within a multimodal pain management strategy, has demonstrated effectiveness in diminishing the reliance on opioids after cardiac surgery.[208] It is also important to maintain the blood glucose level under 180 mg/dL using continuous insulin infusion, both intraoperatively and in the early postoperative period. This practice has a COR 1 recommendation from the current ACC/AHA/SCAI Guideline for Coronary Artery Revascularization and has been shown to reduce the risk of sternal wound infection.[21,209] Finally, early extubation should be prioritized once the patient is awake and hemodynamically stable with minimal chest tube output. Some centers extubate stable patients in the operating room. Pulmonary hygiene (deep-breathing exercises while maintaining sternal precautions) is important to prevent atelectasis, pneumonia, and reintubation.[210]

Discharging patients from the ICU after CABG necessitates a multifaceted approach, ensuring stability of vital signs and good cardiac and respiratory function as well as confirming proper wound healing and renal function. Before departing the ICU, central lines and catheters are often removed. Chest tubes are removed according to protocols. Ensure minimal chest tube drainage (<400 mL of daily output) and no evidence of clinically significant pulmonary effusion or pneumothorax before removal.[211] It is crucial that the patient demonstrates adequate pain management, gastrointestinal function, and mobility, aligning with their preoperative baseline. Psychological readiness and a strong support system are also important for a smooth transition from ICU care and have been associated with long-term survival after CABG.[212,213]

Finally, a comprehensive review by a multidisciplinary team is essential to validate the patient's readiness for discharge. This process is supported by guidelines from authoritative bodies, including the ACC Foundation, the AHA, and the Enhanced Recovery After Surgery Society, which emphasize a patient-centered approach in the postoperative management and discharge planning for CABG patients.[21,211]

CARDIAC REHABILITATION AND RISK FACTOR MODIFICATION AFTER CORONARY ARTERY BYPASS GRAFTING

Cardiac rehabilitation (CR) post-CABG has been consistently shown to improve patient outcomes, particularly through exercise-based programs, patient education, and behavior modification.[214] Spiroski et al. (2017) demonstrated that a structured rehabilitation program, including cycling and walking, significantly improved exercise tolerance, respiratory exchange ratios, and peak maximal oxygen uptake (VO$_2$) in patients after MI and CABG. These benefits were observed after a 3-week inpatient program and continued to improve throughout a 6-month outpatient program, highlighting the sustained positive impact of CR on patient recovery.[215]

Timely access to CR is crucial for maximizing these benefits. In addition to physical activity, CR may assist in fostering adherence to healthy lifestyles and management of chronic and comorbid diseases associated with CAD (diabetes, obesity). Marzolini et al. (2015) showed that the median time from CABG to first CR was approximately 80 days. They identified several demographic, environmental, and physiologic factors contributing to the delay in starting CR. Specifically, older age, female sex, unemployment status, less social support, longer drive time to the CR center, lower neighborhood socioeconomic status, and certain health conditions were associated with longer wait times.[216] Crucially, the study established a clear link between longer wait times and less favorable health outcomes. Extended wait times correlated with less improvement in cardiopulmonary fitness, lower program adherence, increased body fat percentage, and a higher resting heart rate. These findings are pivotal, considering that timely CR has been associated with reduced mortality rates and improved cardiovascular fitness.

Therefore, the 2021 ACC/AHA/SCAI Guideline for Coronary Artery Revascularization has a Class 1, Level A recommendation for CR referral (home or center based) before hospital discharge or during the first outpatient follow-up appointment.[21] Additionally, there is a COR 1 recommendation that all patients should be educated in a timely manner about the need to modify their cardiovascular risk factors after revascularization to reduce further adverse cardiac events. Specifically, patients should understand that continued tobacco use (including e-cigarettes) is a major risk factor for stent thrombosis and other major cardiovascular events.[21]

GUIDELINE-DIRECTED MEDICAL THERAPY AFTER CORONARY REVASCULARIZATION

Antiplatelet Therapy With Aspirin in Coronary Artery Bypass Grafting

Bleeding during and shortly after CABG is a significant concern, making the assessment of bleeding risks critical when considering antiplatelet medications. Historical data indicate that aspirin enhances the patency of vein grafts. A significant body of evidence continues to support the use of aspirin to prevent further ischemic events and maintain graft patency.[217,218] There is a Class 1, Level A recommendation regarding the initiation of aspirin (100–325 mg daily) within 6 hours of CABG. In a subset of patients, DAPT with aspirin and ticagrelor or clopidogrel may be reasonable (COR 2b) to promote vein graft patency.[21]

Use of Oral β-Blocker After Revascularization

There is no evidence to support the chronic use of oral β-blockers after revascularization in patients with SIHD who otherwise have a normal LVEF (COR 3). However, oral β-blockade is highly recommended (COR 1) in the postoperative period after CABG to reduce the incidence and complications of postoperative AF, given that new-onset AF is associated with a fourfold increased risk of stroke.[21,219]

PSYCHOLOGICAL CARE AFTER CORONARY REVASCULARIZATION

Despite the recognition of depression as a prevalent comorbidity after revascularization, affecting up to 20% of patients, its management remains inadequate.[220] This is concerning because depression is a known independent predictor of cardiovascular morbidity, mortality, and increased healthcare costs after revascularization.[213] Based on this, the 2021 ACC/AHA/SCAI Guideline for Coronary Artery Revascularization indicates that it may be reasonable to screen patients who have undergone coronary revascularization and refer and treat them when indicated to improve quality of life and recovery (COR 2b). This recommendation was less strong because of the results of one large trial of 1500 patients with ACS that did not show significant benefits (quality of life, depression-free days, depressive symptoms, mortality rate, or patient-reported harms) after screening and treatment for depression.[221] However, there is a Class 1 recommendation for the treatment of patients (cognitive behavioral therapy, psychological counseling, and/or pharmacologic interventions) who have undergone coronary revascularization and have been diagnosed with depression, anxiety, or stress to improve quality of life and cardiac outcomes.[21]

DISPARITIES IN THE SURGICAL TREATMENT OF CORONARY ARTERY DISEASE

Many studies have described disparities in care delivery and the rates of morbidity and mortality across racial, sex, and ethnic minorities (e.g., Black and South Asian patients have poor cardiovascular outcomes compared with White patients) in the United States.[222] Furthermore, the persistent underrepresentation of minority ethnic groups and females in RCTs calls into question the generalizability of important findings. It is clear that the strongest evidence for guidelines derives from RCTs.[222] For this reason, many have called for practical measures to improve the enrollment and retention of racial and ethnic minorities in clinical trials.[21] In addition, treatment decisions in patients undergoing coronary revascularization should be based on clinical indication, regardless of sex, race, or ethnicity, and efforts to reduce disparities are warranted (COR 1).[21]

IMPORTANCE OF PERFORMANCE MEASURES AND DATABASE PARTICIPATION IN CORONARY REVASCULARIZATION

In cardiac surgery, quality and performance assessments are critical. Although these concepts involve a complex interplay of institutional structure, processes, and patient-specific risk-adjusted outcomes and can seem demanding at times, it is imperative to have surgeon and interventionist understanding and adherence.[59,223] With respect to coronary revascularization, *structure* pertains to the characteristics of the surgeon, interventionist, and clinical team or the environment where the coronary revascularization takes place, acting as the initial platform from which care processes begin. *Process* involves the actual delivery of care (revascularization) and how the specific steps taken during the procedure affect the final result. *Outcomes* represent the final achievements of the procedure (PCI or CABG) and are often seen as the most concrete element in the cycle of enhancing quality.[223] The 2023 AHA/ACC Clinical Performance and Quality Measures for Coronary Artery Revascularization Guideline highlights 15 performance measures, 5 quality measures, and 2 structural measures. The performance and quality measures form the bedrock of the 2021 ACC/AHA/SCAI Guideline for Coronary Revascularization and have been heavily highlighted in this chapter. However, the two structural measures from the Clinical Performance and Quality Measures Guideline focus on (1) the importance of meticulous preprocedural assessment for patients presenting for coronary revascularization and the role of the heart team and (2) the benefit of registry participation.[59]

Among other benefits, performance measures and database affiliation provide clinical benchmarks and promote continuous improvement in patient care. These measures, including morbidity and mortality rate, are directly linked to patient outcomes. The role of specialized databases in CABG surgery is crucial for comprehensive data analysis and benchmarking. Registries such as the STS Adult Cardiac Surgery Database offer extensive data, enabling centers to reference their performance and implement evidence-based strategies to enhance patient care. Participation in such databases ensures that centers are aligned with national and international standards, paving the way for improved patient outcomes and care quality.[21,59]

In summary, performance measures and database participation form the cornerstone of ongoing quality improvement in CABG surgery. These tools not only provide a framework for evaluating and enhancing patient care but also promote a culture of transparency and continuous quality improvement.

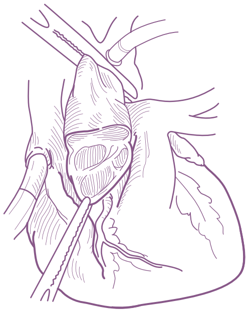
112 CHAPTER



Acquired Heart Disease: Valvular

Marc R. Moon, Puja Kachroo, and Todd K. Rosengart

OUTLINE

History of Heart Valve Surgery
Valve Anatomy
  Surgical Anatomic Relationships
Etiology and Pathology of Valvular Heart Disease
  Rheumatic Heart Disease
  Endocarditis
General Operative Approach
  Conduct of Heart Valve Surgery
  Prosthetic Valves
Specific Valvular Lesions
Transcatheter Aortic Valve Replacement
Aortic Regurgitation or Insufficiency
Mitral Stenosis
Mitral Regurgitation
Tricuspid Regurgitation and Other Right-Sided Valvular Disease
Mixed Valve Disease

The heart contains four valves that regulate the directional flow of blood through its chambers. Effective cardiac pumping activity is dependent on the properly timed functioning of these valves. The atrioventricular (AV) valves (mitral and tricuspid) close during systole to prevent backflow into the atria during ventricular ejection. During diastole, the semilunar valves (aortic and pulmonic) close to prevent backflow into the ventricles as they fill from the atria.

The heart beats an average of 100,000 times per day and more than 2.5 billion times over an average lifespan. Given the great number of open-close cycles of the valves and the relative infrequency of cardiac valvular heart disease, a reported prevalence of less than 2% of the population,1 it must be concluded that the valvular structures are exceedingly well adapted to meet these physical demands.

The cardiac valves may, nevertheless, succumb to injury or degeneration as a result of a variety of pathophysiologic processes, and valvular dysfunction can result in significant morbidity and mortality. In the past century, extended life and improved health for millions with cardiac valve disease have been made possible by the advent of open surgical valve repair and replacement procedures, most notably after the widespread application of cardiopulmonary bypass in the 1950s and 1960s. More recently, percutaneous interventions to repair or replace damaged valves have been increasingly used to deliver these benefits without requiring cardiopulmonary bypass.

HISTORY OF HEART VALVE SURGERY

Notwithstanding investigations in the 19th century into the treatment of rheumatic heart disease (RHD), the modern history of heart valve surgery can be traced back to Sir Thomas Lauder Brunton, a Scottish physician. In 1902, he proposed a technique for closed repair of stenotic rheumatic mitral valve (MV) disease with access to the valve gained by passing a dilator through the left ventricular (LV) wall. Unfortunately, this idea was shunned by Brunton's colleagues as reckless and was never attempted clinically. Fortunately, however, Elliot Cutler and Samuel Levine further developed Brunton's early theory and successfully performed the first closed transventricular MV commissurotomy using a tenotomy knife in 1923 after their extensive experimentation in the research laboratories of the Peter Bent Brigham Hospital in Boston. Sir Henry Souttar of England adapted their technique and, in 1925, reported the first successful case of closed digital commissurotomy, inserting the surgeon's index finger through the left atrial (LA) appendage to accomplish mechanical MV dilatation. This procedure was not widely adopted until 1948, after reports by Charles Bailey of Philadelphia and Dwight Harken of Boston of clinically successful closed digital mitral commissurotomies (Fig. 112.1).

Blinded aortic valvular surgery followed a similar course. In 1912, Theodore Tuffier of Paris reported the first clinical attempt to dilate a stenotic aortic valve, pushing his finger against the aorta and invaginating the aortic wall through the valve. Mechanical dilation using an instrument passed retrograde from the innominate artery was reported by Lord Russell Brock of London in 1940. Neither of these efforts gained acceptance, but they paved the way for Horace Smithy of Charleston, South Carolina, who performed the first successful aortic valvotomy in 1948. Three years later, Charles Bailey of Philadelphia reported the first successful aortic valvotomy using a transventricular expanding dilator.

Two major advancements occurring in the 20th century marked the beginning of the modern era of "open" heart valve surgery: the development of a prosthetic valve and the advent of cardiopulmonary bypass. The first successful implantation of a prosthetic valve was performed without bypass and was reported by Charles Hufnagel of Georgetown University in 1952. Given the inability to access the aortic valve in situ, Hufnagel implanted a caged-ball valve into the descending aorta in patients with aortic

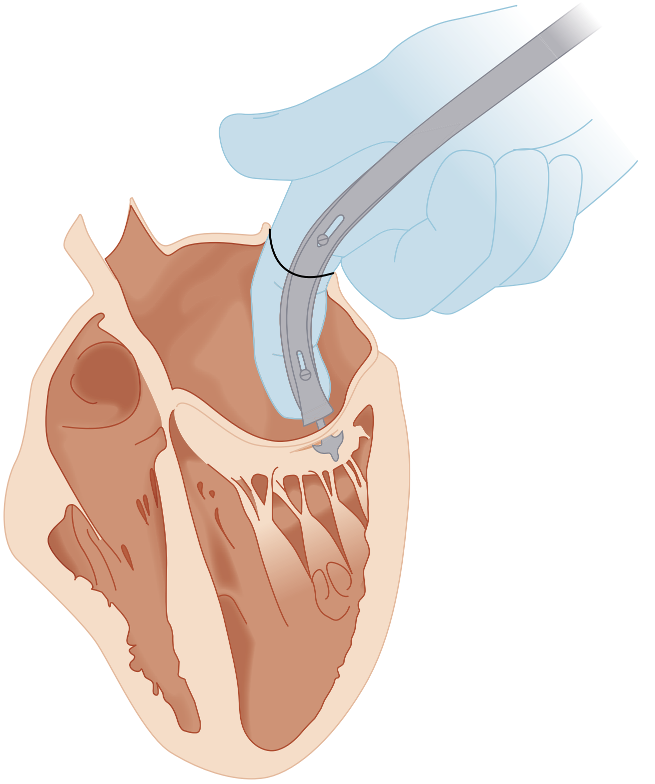


FIGURE 112.1 Closed mitral commissurotomy. Dwight Harken developed a closed mitral commissurotomy procedure to correct rheumatic mitral stenosis, which became the first widespread approach to treating valvular heart disease. (From Muller WH Jr. The surgical treatment of mitral stenosis. *Calif Med.* 1951;75:285-289.)

insufficiency (AI). After the first successful clinical use of cardiopulmonary bypass by John Gibbon at Thomas Jefferson in Philadelphia in 1953, Dwight Harken in 1960 completed the first successful in situ aortic valve replacement using a caged-ball device inserted in place of an excised aortic valve. That same year, Nina Braunwald at Brigham and Women's Hospital in Boston was the first to replace the MV, using a mechanical device made of flexible polyurethane with fabric chordae tendineae. The operation was performed on March 11, 1960, 6 months before Albert Starr and Lowell Edwards in Oregon replaced the MV using a caged-ball prosthesis. Dr. Braunwald was one of the first three females certified by the American Board of Thoracic Surgery in 1961 and, in 1966, was the first female to become a member of the American Association for Thoracic Surgery (AATS), the oldest and most prestigious organization dedicated to surgical diseases of the chest. What followed was an explosion of improvements in prosthetic valve design and surgical implantation techniques, allowing for progressive improvement in outcomes after valve replacement. Next, valve repair was championed by Alain Carpentier of Paris with his Honored Guest Lecture at the AATS Annual Meeting in 1983 titled "Cardiac Valve Surgery—the 'French Correction.'"[2]

In 1986, G. Alain Cribier of Rouen, France, developed and performed the world's first balloon aortic valvuloplasty to treat aortic stenosis, but the long-term results were suboptimal. Stenosis reoccurred fairly rapidly in the majority of patients. Cribier continued to innovate, eventually placing a balloon-expandable stent-mounted prosthetic valve outside a valvuloplasty balloon and inflating it in position at the level of the aortic annulus under fluoroscopic guidance. In 2002, transcatheter valve replacement was introduced by Cribier. Transcatheter edge-to-edge repair (TEER) of the MV shortly followed in the early 2000s. Currently, transcatheter tricuspid valve repair and mitral and tricuspid valve replacement therapies are under development.

VALVE ANATOMY

The four human heart valves follow similar early embryologic development, beginning at 4 weeks of gestation with formation of the valve primordia in the primitive heart tube. This development is closely linked to the division of the heart tube into its chambers, including septation of the outflow tract (truncus arteriosus) and fusion of the AV canal cushions. Most of the cells, which migrate to form the valve primordia, originate from the endocardial cushion, although epicardial and neural crest cells also appear to contribute. The valve primordia grow and elongate between 20 and 39 weeks of gestation, thinning to form leaflets and cusps. In late gestation and early after birth, these structures become stratified into highly organized layers to differentiate into formal valve leaflets. Valve maturation and remodeling continue into the juvenile stages of life.

All four cardiac valves are supported by internal plates of dense collagen-, proteoglycan-, and elastin-rich connective tissue that are continuous with the fibrous skeleton at the base of the heart (Fig. 112.2). The extracellular matrix of each valve is organized into three layers: the fibrosa, made of fibrillar collagen; the spongiosa, made of proteoglycans; and an elastin layer termed the *atrialis* (on the AV valves) or the *ventricularis* (on the semilunar valves), in reference to the heart chamber the layer faces (Fig. 112.3). Covered in a thin layer of epithelium, the atrialis or ventricularis forms the surface over which blood flows through the valve, with the underlying spongiosa and fibrosa contributing structural support.

The aortic and pulmonic semilunar valves are freestanding structures seated atop the outflow tracts of their respective ventricles. They do not have discrete annuli but are instead attached in a curvilinear fashion to the wall of the aorta or pulmonary artery at their junction with the LV or right ventricular (RV) outflow tracts, respectively. These valves have three leaflets or cusps with a semilunar shape from which they derive their name (Fig. 112.4). Each cusp is in turn made up of four components: the hinge region where the cusp connects to the annulus; the belly, which makes up the majority of the cusp; the coapting surface at the cusp periphery; and the annulus, which is where the cusps attach to the ventriculoaortic junction.

In contrast to the freestanding semilunar valves, the mitral and tricuspid valves exist within a functional valve complex composed of discrete, fibrous annular rings (the annuli fibrosis); the valve leaflets; fibrous chordae tendineae; and papillary muscles. The fibrous chordae tendineae arise from the leaflet free edges (marginal or primary chordae) or undersurface (intermediate or secondary chordae), with basal (tertiary) chordae also arising from the posterior leaflet base and annulus. These chordae attach to intraventricular papillary muscles, which in turn arise from the ventricular myocardium. These additional support structures allow the AV valves to maintain the high transvalvular pressures to which they are exposed during systole.

The MV proper has two leaflets possessing approximately equal surface area (Fig. 112.5). The square-shaped anterior leaflet originates from the anterior one-third of the valve annulus. The posterior mitral leaflet is less tall but is wider than the anterior leaflet,

FIGURE 112.3 Valve histology. (A) Aortic valve. (B) Mitral valve. The mature valve is composed of a highly organized extracellular matrix, which is compartmentalized into three layers: the fibrosa, made of fibrillar collagen; the spongiosa, made of proteoglycans; and either the ventricularis of the semilunar valves or the atrialis of the atrioventricular valves, made of elastin fiber. (From Combs MD, Yutzey KE. Heart valve development: regulatory networks in development and disease. *Circ Res.* 2009;105:408-421.)

attaching to the posterior two-thirds of the annulus. The anterior and posterior leaflets each have three scallops (A1, P1, etc.), based on indentations found in the posterior leaflet. Of note, although the posterior leaflet segments are quite easy to delineate, the anterior leaflet segments are not clearly differentiated. In comparison, the tricuspid valve is composed of anterior, posterior, and septal leaflets, of which the anterior leaflet is the largest. Recently, with closer echocardiographic investigation of the tricuspid valve to assess and further the success of transcatheter repair therapies, there is increasing variability noted in leaflet morphology, including number and location of supernumerary leaflets or scallops.

The fibrous trigones are important landmarks during MV surgery at approximately the 10 o'clock (anterior) and 2 o'clock (posterior) positions in the surgeon's view (from the right side of the operating table). These landmarks identify the fibrous portion of mitral annulus between the mitral and aortic valves that does not stretch when the annulus pathologically dilates. The remaining "posterior" annulus is not fibrous and therefore can dilate with pathologic change. The MV also has two commissures between the anterior and posterior leaflets, the anterolateral commissure, at approximately 9 o'clock, and the posteromedial commissure, at approximately 3 o'clock.

The MV is supported by an anterolateral and posterolateral papillary muscle, each of which sends chordae to both anterior and posterior leaflets. In comparison, the tricuspid valve is supported by a large anterior papillary muscle that sends chordae to the anterior and posterior leaflets and a variable medial or posterior papillary muscle that provides chordae to the posterior and septal leaflets. The RV septal wall also provides chordae to the anterior and septal tricuspid leaflets, but there is no formal septal papillary muscle.

As suggested by their anatomy, the semilunar and AV valves differ in the mechanisms employed to maintain coaptation. The

FIGURE 112.5 Anatomy of the atrioventricular valves. The atrioventricular valves are composed of leaflets arising from a distinct fibrous annulus. The depicted mitral valve is composed of an anterior and posterior leaflet, each subdivided into three scallops. (With permission, courtesy Decker Medicine LLC.)

semilunar valve cusps depend largely on mechanisms intrinsic to the cusps themselves. During diastole, the cusps fall passively to the center and seal the orifice by coapting with the corresponding midpoint nodules on adjoining cusps. The AV valves, on the other hand, are tethered in their closed position by their chordal attachments to the papillary muscles, which contract during systole to maintain leaflet coaptation and prevent leaflet prolapse into the atria (Fig. 112.6).

Surgical Anatomic Relationships

The semilunar and AV valves are closely invested with each other at the base of the heart, with both the electrical conduction and coronary arterial systems in close proximity and at risk during cardiac valve procedures and when infections may extend from the valves to invade surrounding structures (Fig. 112.7). The aortic valve cusps, for example, are named for their intimate relationship with the coronary arteries (i.e., the right coronary, left coronary, and noncoronary [posterior] cusps), which arise from the coronary ostia in the sinuses of Valsalva. The sinuses of Valsalva are gentle dilatations of the aorta just distal to the valve that direct backward eddy current flow into the ostia when the valve leaflets are closed.

In direct continuity with the left and noncoronary cusps of the aortic valve, from about the 5 o'clock to the 8 o'clock position, is the fibrous trigone of the anterior leaflet of the MV (Fig. 112.8). The noncoronary cusp of the aortic valve and the anterior leaflet of the MV are therefore at risk of injury during mitral and aortic valve surgery, respectively, if sutures bites are taken too deep during valve replacement. Likewise, the AV node lies embedded in the top of the ventricular membranous septum, just beneath the commissure between the noncoronary and right coronary aortic leaflets, from the 3 o'clock to the 5 o'clock position. The remaining circumference of the aortic annulus rests on ventricular muscle and is relatively free anatomically from relevant surgical injury during aortic valve surgery.

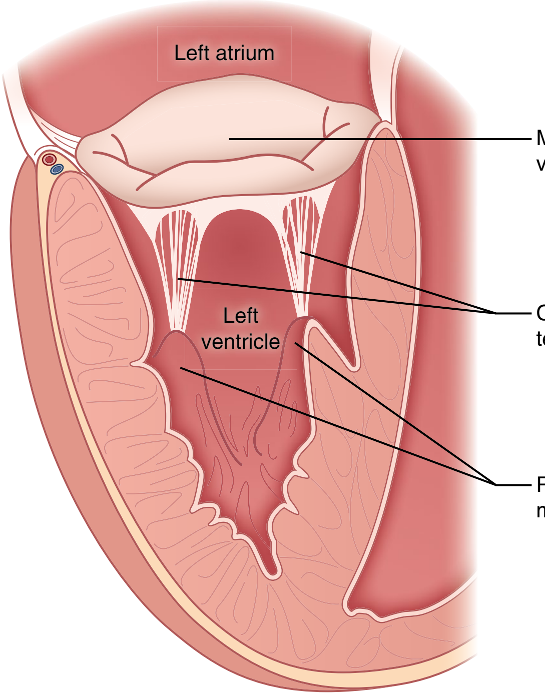

FIGURE 112.6 Subvalvular apparatus of the atrioventricular valves. The mitral and tricuspid valves are supported by a robust subvalvular apparatus featuring the chordae tendineae that tether the leaflets and annuli to the papillary muscles, which contract during systole to maintain leaflet coaptation and prevent leaflet prolapse into the atria. (From Mount Sinai, Mitral Foundation. https://www.mitralvalverepair.org/papillary-muscles-and-left-ventricle. Accessed April 7, 2025.)

The MV bears three classically important surgical anatomic relationships. (1) The posterior leaflet is in continuity with the posterior LV wall. Deep (posterior) to the posterior leaflet lies the AV groove (6 o'clock to 8 o'clock) that contains the circumflex coronary artery and the coronary sinus, which are thereby at risk of surgical injury. (2) The AV node and bundle of His lie deep to the posteromedial commissure of the MV, with errant sutures having potential to cause complete AV conduction block, although this is rare. (3) The noncoronary sinus and cusp of the aortic valve lie behind the fibrous trigone (10 o'clock to 2 o'clock) and can also be injured with deep suture bites (Fig. 112.9).

Tricuspid valve surgery also entails risk to the AV node and bundle of His. The anteroseptal commissure of the tricuspid annulus is positioned on the opposite side of the membranous septum from the MV. The AV node lies within the "triangle of Koch," anatomically defined by the septal leaflet of the tricuspid valve anteriorly, the tendon of Todaro (a thick muscle band along the atrial septum) posteriorly, and the coronary sinus inferiorly by the posteroseptal commissure of the valve. The central fibrous body containing the bundle of His runs superior to the triangle as it passes by the anteroseptal tricuspid commissure and ends in the AV node within the triangle (Fig. 112.10).

The anatomic relations of the pulmonary valve generally do not present much in the way of surgical concern unless one plans to harvest the pulmonic valve for a complex aortic valve replacement technique called the *Ross procedure,* where the aortic valve is replaced with the autologous pulmonary valve and the RV outflow tract is replaced with a cadaveric homograft. The left coronary artery and its first septal branch run directly beneath the posterior area of resection when harvesting the pulmonary valve, and care must be taken to prevent injury.

ETIOLOGY AND PATHOLOGY OF VALVULAR HEART DISEASE

The cardiac valves may become impaired through two fundamental forms of dysfunction, stenosis and insufficiency. Valvular stenosis is an obstruction to forward flow resulting from incomplete opening of the valve. Valvular insufficiency, also referred to as *regurgitation* or *incompetence,* describes backward flow through a valve when its cusps or leaflets are unable to obtain or maintain coaptation. Both stenosis and insufficiency may exist simultaneously in any one valve.

Valvular stenosis is almost always caused by a primary abnormality of the cusp or leaflet from a chronic disease process. Regurgitation may be caused by an acute or chronic disease process affecting the valve itself or may be secondary to a structural abnormality of associated supporting structures, such as the great arteries (aortic and pulmonic valves affected), annuli fibrosis (aortic, mitral, and tricuspid valves affected) and chordae tendineae, papillary muscles, or ventricular myocardium (mitral or tricuspid valves affected) (Table 112.1).

The hemodynamic hallmark of cardiac valve stenosis is the occurrence of an increased pressure gradient between an upstream pumping chamber and downstream receiving chamber or great artery. This increased gradient is necessary to maintain the

baseline flow rate through the valve as a result of the increased resistance to laminar flow introduced by the smaller effective cross-sectional area of the stenotic valve orifice, as described by Poiseuille law (flow α Δp/resistance, where Δp signifies pressure gradient). The hemodynamic hallmark of regurgitant valvular disease is the retrograde flow of blood from downstream structures (ventricle or great vessel) into an upstream chamber during the diastolic interval, during which the malfunctioning valve should normally be closed. Uncompensated lesions, either stenotic or regurgitant forms, cause an increase in upstream chamber afterload and consequent wall stress. This occurs either during ventricular systolic ejection against the resistance of stenotic valves

or with increased chamber filling by regurgitant volumes peaking at the end of diastole.

Two compensatory mechanisms provide robust reserves in cardiac function before the volume and pressure overload stresses of valve disease translate into significant cardiac physiologic derangements. The first, described by the Frank-Starling law (Fig. 112.11), produces increases in ventricular contractile force as a function of end-diastolic volume (EDV), or preload, to enhance stroke volume and ventricular emptying. The second involves stress-induced ventricular hypertrophy that leads to increased wall thickness. By decreasing chamber radius (volume) or increasing wall thickness, the ventricles can lower wall stress, as described by the Laplace law: wall stress α (pressure × radius)/(2 × wall thickness). Decreased wall stress, in turn, translates into decreased myocardial work and oxygen demand and improved cardiac function. Ultimately, as cardiomyopathy progresses, contractile function progressively diminishes past the ideal sarcomere length of 2.2 micrometers, whereby heart failure (HF) ensures.

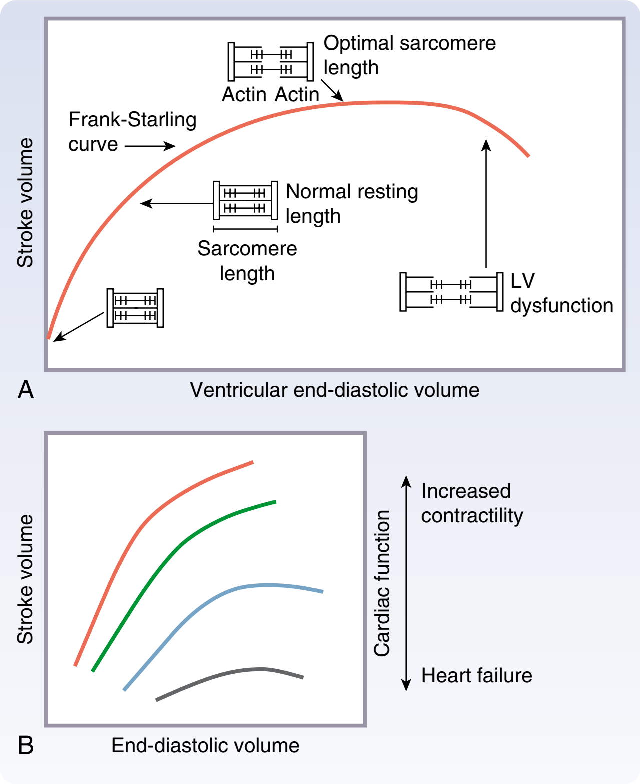

FIGURE 112.11 Frank-Starling curve. The Frank-Starling law describes a generally linear relationship between increasing end-diastolic volume, or preload, and generated ventricular pressure. (A) Shifts in volume change generated pressure or stroke volume along a given pressure-volume curve. (B) Cardiomyopathy shifts curve downward. *LV,* Left ventricle. (From Hanft LM, Korte FS, McDonald KS. Cardiac function and modulation of sarcomeric function by length. *Cardiovasc Res.* 2008;77(4):627–636. doi:10.1093/cvr/cvm099.)

Rheumatic Heart Disease

Degenerative disease remains the more common cause of valve disease in the developed world. On the other hand, rheumatic fever with ensuing RHD remains the most common, albeit decreasing, cause of valvular dysfunction in underdeveloped countries and those with limited healthcare access. Acute rheumatic fever develops because of a cross-reactive host immune response exhibited by genetically susceptible individuals in response to group A β-hemolytic streptococcal infection acquired during the first decade of life. This pathologic process is driven by molecular mimicry between streptococcal proteins and host cardiac proteins such as laminin.[3] In a small minority of patients, this initial response causes clinically evident inflammation in the cardiac valves and/or conduction system several weeks after the streptococcal infection. Surgical intervention to "peel" the inflammatory material off the valve can be effective in improving valve function, at least for a limited time.

Rarely, acute rheumatic valvulitis can result in severe acute mitral regurgitation (MR) and may be associated with other manifestations of carditis, such as AV conduction abnormalities or pericarditis. In developed countries, however, the typical presentation is that of chronic RHD, which silently develops as ongoing valvular damage occurs from repeated exposures to streptococcal infection and ongoing damage to a deformed valve in adolescence and adulthood.

Chronic RHD most commonly presents as either MV stenosis (see later) or mixed valve lesions (stenotic and regurgitant). Mixed

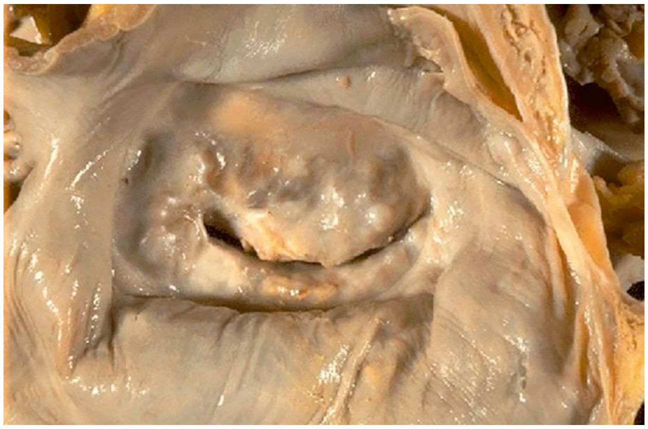

FIGURE 112.12 Mitral valve pathology in rheumatic heart disease. Typical pathology of rheumatic mitral valve disease presenting as a pathognomonic, mixed stenotic/regurgitant "fish mouth" funnel valve lesion, often associated with fusion and shortening of the leaflets and chordae tendineae. (From http://library.med.utah.edu/WebPath/CVHTML/CV061.html.)

stenotic and regurgitant mitral pathology takes the form of a pathognomonic "fish mouth" funnel valve lesion as a consequence of fusion of the leaflets at the commissures that hinders opening of the leaflets. This is associated with fusion and shortening of the chordae tendineae (Fig. 112.12). Sclerosis induced by chronic inflammation reduces leaflet mobility to prevent complete opening of the valve during diastole and adequate coaptation to close the valve during systole. Clinically apparent HF typically develops from these RHD lesions in the third or fourth decade of life as a result of progressive valve dysfunction and/or exhaustion of compensatory mechanisms.[4]

RHD next most frequently leads to aortic valve stenosis or regurgitation through a similar pattern of chronic inflammation. The resultant sclerosis impairs valve opening (narrowed orifice) and valve closing (gap through which regurgitant flow from the aorta to ventricle can occur). Tricuspid regurgitation (TR) is also a common secondary valvular abnormality in RHD because of upstream hemodynamic stresses caused by MS. The ensuing pulmonary hypertension leads to dilation of the right ventricle, especially the free wall, and tricuspid annulus compromising tricuspid valve leaflet coaptation.

Endocarditis

Endocarditis is a relatively common cause of aortic, mitral, and tricuspid valve regurgitation.[5,6] The incidence of endocarditis varies from 3 to 10 episodes per 100,000 person-years. Endocarditis typically causes valvular insufficiency by progressive inflammatory destruction of the affected valve and surrounding structures. Less frequently, endocarditis can cause functional valve stenosis, with valve orifice obstruction developing from endocarditic vegetations, masses of platelets, fibrin, microcolonies of microorganisms, and inflammatory cells.

Endocarditis with acute AI carries a relatively high mortality compared with other valve lesions. Endocarditis may affect previously normal valves, but it typically affects valves deformed by congenital or rheumatic disease, degenerative processes such as calcification, or previously replaced prosthetic valves. Infectious endocarditis not related to intravenous drug use is usually left-sided, reflecting the normal distribution of such preexisting valvular disease. Endocarditis resulting from intravenous drug use most often affects the tricuspid valve.

The pathophysiology of endocarditis is typically initiated by platelets and fibrin deposition on normal or deformed valves occurring as part of a normal healing process after disruption of the valvular endothelium caused by hemodynamic or metabolic injuries. Endocarditis results from subsequent seeding onto damaged valves by microbiologic organisms after bacteremia or fungemia episodes, most commonly staphylococci, streptococci, or enterococci.

Acute endocarditis, increasingly affecting normal valves, may follow an aggressive course with leaflet perforation or more extensive destruction of the leaflet and/or surrounding support structures, resulting in acute valvular regurgitation. With subacute or chronic presentations of endocarditis, valve insufficiency may result from residual leaflet deformities caused by fibrotic healing of endocarditic lesions. The growth of large vegetations may also uncommonly lead to improper leaflet coaptation and valve regurgitation as well.

GENERAL OPERATIVE APPROACH

The specific surgical approach will be described for each of the various valvular lesions in the following sections. In general, surgery for valvular heart disease is today associated with excellent short- and long-term outcomes, with some evidence suggesting even better outcomes for surgery performed at high-volume centers.[7] Operative mortality, which in the modern era is generally $<5\%$ for almost all types of valve pathology, can now be predicted using several widely available multivariable risk calculation scoring systems.[8,9]

Operative mortality is predicted by risk factors such as age, female sex, emergency surgery, symptomology, concomitant procedures, and decreased ejection fraction (EF), along with comorbidities such as diabetes mellitus, renal dysfunction, pulmonary disease, peripheral vascular disease, and prior operation (Table 112.2). Typically, isolated tricuspid valve surgery is associated with the highest operative mortality risk (primarily related to coexistent cardiac pathophysiology), followed by MR and AI. Surgery for AS and MS offers the best operative mortality outcomes. Complications most frequently associated with surgery for valvular heart disease include infection, bleeding, stroke, conduction block requiring permanent pacemaker, and HF (Table 112.3).

Long-term outcomes and resolution of ventricular hemodynamic pathophysiology can generally be predicted by the duration and/or severity of symptoms associated with valvular disease, extent of ventricular dysfunction, and the presence and severity of pulmonary hypertension.[10,11] Complete hemodynamic recovery from valvular disease, including resolution of ventricular hypertrophy and enlargement, may be seen as early as the first several weeks postoperatively but may progress for up to a year after surgery. Long-term complications frequently associated with valve surgery include thromboembolic events leading to strokes, structural valve degeneration, progressive paravalvular leaks, bleeding associated with anticoagulation, and endocarditis.

Conduct of Heart Valve Surgery

The use of cardiopulmonary bypass and cardioplegic arrest of the heart is standard when performing open-heart procedures on the cardiac valves (unlike in percutaneous interventions, as described later). A full midline median sternotomy has traditionally been the predominant means to obtain wide exposure for heart valve surgery. However, various minimally invasive approaches are now also used and have proven to be equally safe and effective

TABLE 112.2 European System for Valvular Surgery Operative Risk Evaluation (EuroSCORE)

PATIENT-RELATED FACTORS	DEFINITION	SCORE
Age	Per 5 years or part thereof over 60 years	1
Sex	Female	1
Chronic pulmonary disease	Long-term bronchodilators/steroids	1
Extracardiac arteriopathy	Claudication, carotid occlusion or >50% stenosis, intervention on abdominal aorta, limb arteries, carotids	2
Neurologic dysfunction	Severely affecting ambulation or day-to-day functioning	2
Previous cardiac surgery	Requiring opening of the pericardium	3
Serum creatinine	>200 mmol/L preoperatively	2
Active endocarditis	Antibiotic treatment for endocarditis at the time of surgery	3
Critical preoperative state	Ventricular tachycardia, fibrillation, aborted sudden death; preoperative cardiac massage, ventilation, inotropic support, IABP, or acute renal failure (anuria or oliguria <10 mL/h)	3
Cardiac-Related Factors		
Unstable angina	Rest angina requiring intravenous nitrates preoperatively	2
LV dysfunction	Moderate or LVEF 30%–50%	1
	Poor or LVEF <30	3
Recent myocardial infarct	Within 90 days	2
Pulmonary hypertension	Systolic PA pressure >60 mm Hg	2
Operation-Related Factors		
Emergency	Carried out on referral before next working day	2
Other than isolated CABG	Major cardiac procedure other than or in addition to CABG	2
Surgery on thoracic aorta	For disorder of ascending, arch or descending aorta	3
Postinfarct septal rupture		4

compared with traditional open approaches. Specific minimally invasive approaches include partial upper or lower sternotomies, right anterior (second to fourth interspaces) thoracotomies with direct or thoracoscopic visualization, and robotic-assisted techniques (Fig. 112.13). These approaches have been associated with decreased transfusion, wound infection, hospital stay, and atrial fibrillation, along with quicker recovery and improved cosmesis.

Prosthetic Valves

Prosthetic heart valves used currently are typically made from a synthetic material (mechanical valves; Fig. 112.14A), allogeneic biologic tissue (bioprosthetic valves; see Fig. 112.14B), or (cadaveric) homografts. Each has distinct advantages and disadvantages. Anticoagulation with a vitamin K antagonist (warfarin) and monitoring of the international normalized ratio (INR) is recommended in all patients with mechanical prosthetic valves and typically for the first 3 months after bioprosthetic MV implants (Table 112.4).[10] Aspirin may be added to warfarin therapy to reduce rates of major embolism, stroke, and overall mortality.

The current generation of mechanical valves, nearly all bileaflet pyrolytic carbon in design, can be expected to provide an extremely low incidence of structural deterioration but have a 0.6% to 2.3% per patient-year incidence of thromboembolic complications.[10,12] The need for anticoagulation with warfarin is associated with approximately a 1% annual risk of bleeding complications. Both bleeding and thromboembolic complications may be reduced through more frequent (e.g., weekly) INR surveillance and/or home testing.[13]

Bioprosthetic valves are almost universally fabricated from preserved (bovine) pericardium or from porcine valves specially harvested for this use. Modern antimineralization and tissue preservation techniques involving treatment of valves with alpha-oleic acid reduce leaflet calcification and typically provide ~90% freedom from structural valve deterioration and reoperation at 10 years in patients over 65 years of age.[14] Failure rates may be higher in younger patients as a result of greater hemodynamic stresses and/or metabolic (i.e., calcium turnover) rates. Recent studies demonstrate potential for improved long-term results with contemporary tissue valves, even in younger patients.[15,16]

Based upon the previously described considerations, some surgeons now recommend implantation of bioprosthetic valves in patients less than the recommended class IIa cutoff of 50 to 65 years of age, accepting the risk of reintervention by open or

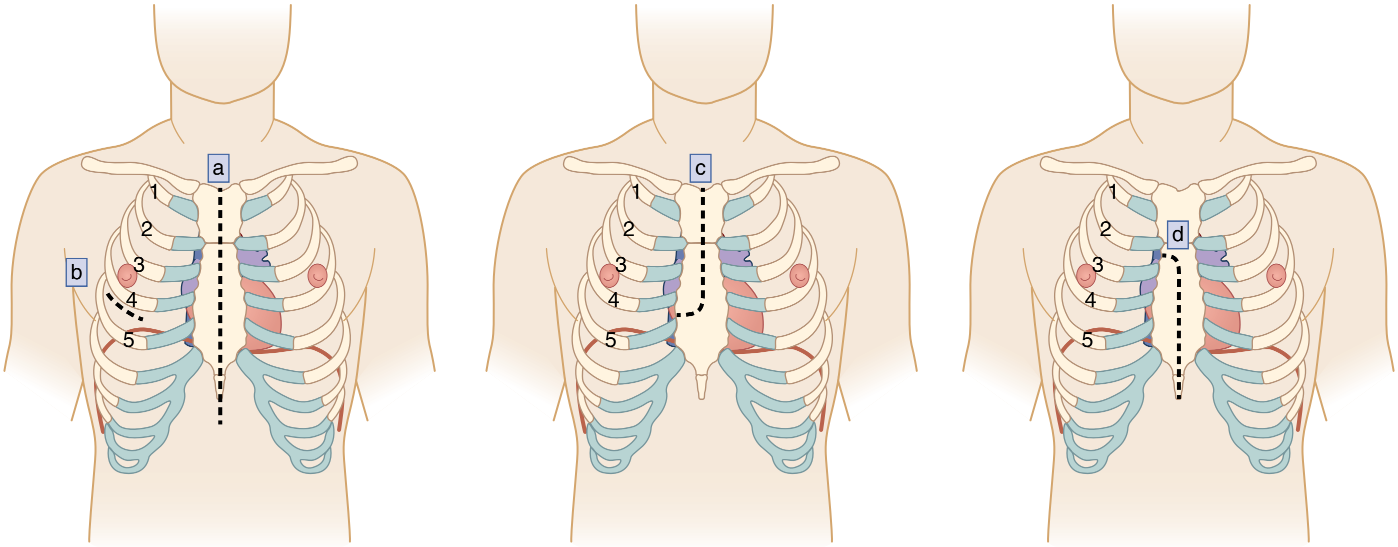

FIGURE 112.13 Surgical access for valvular heart surgery. Median sternotomy *(a)* versus minimally invasive access via minithoracotomy *(b)* or partial upper *(c)* or lower *(d)* sternotomy. (From Byrne JG, Leacche M, Vaughan DE, et al. Hybrid cardiovascular procedures. *JACC Cardiovasc Interv.* 2008;1:459-468.)

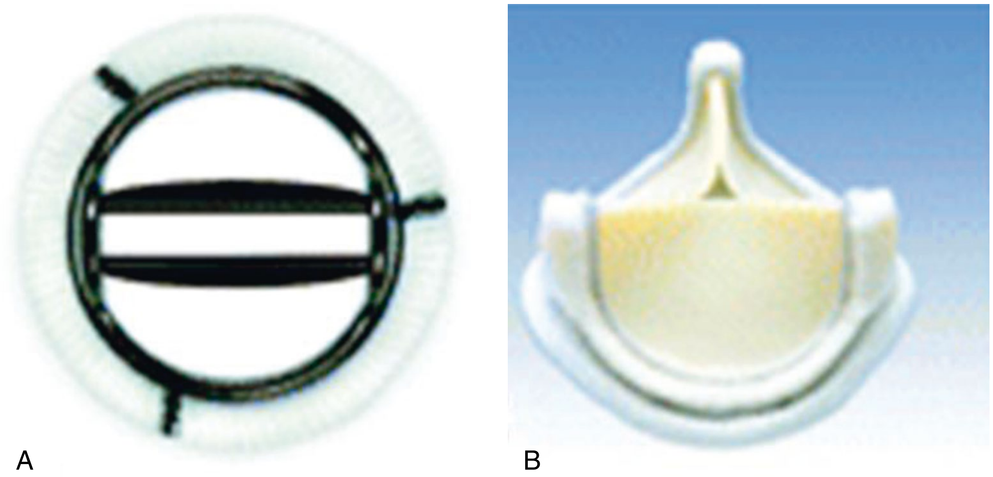

FIGURE 112.14 Prosthetic valves. Prosthetic heart valves most often implanted are made from (A) synthetic material, such as pyrolytic carbon (mechanical valve), or (B) allogeneic biologic tissue, such as bovine pericardium (bioprosthetic valve). (From Pibarot P, Dumesnil JG. Prosthetic heart valves: selection of the optimal prosthesis and long-term management. *Circulation.* 2009;119:1034-1048.)

percutaneous technique as being less than the lifelong risk of anticoagulation or mechanical valve thromboembolism. The decision for a mechanical versus a bioprosthetic valve is complex. Many factors, including patient age, likelihood of pregnancy, and indications or contraindications to anticoagulation, must be considered. In contrast to the more complex xenograft stentless aortic bioprosthetic roots and homograft implants, technical considerations in prosthetic valve implantation are generally considered similar between valve types.

Excellent early and long-term survival outcomes can be expected after valve implantation (Table 112.5; see also Table 112.3).[10,17–28] One of the most frequent and dangerous complications of valve implantation is prosthetic valve endocarditis (PVE), which is 50 times more likely to occur than endocarditis in the general population with native valves. PVE typically requires prosthetic valve excision and re-replacement, especially when PVE is caused by virulent organisms such as *Staphylococcus aureus* or fungi, although intravenous antibiotic or antifungal therapy alone may occasionally be used to sterilize lesions in high-risk individuals.[5,6] Even with appropriate antibiotic therapy and surgical intervention, PVE carries a mortality rate of up to 40% at 1 year. Accordingly, patients with prosthetic valves, similar to individuals at increased risk for native valve endocarditis, should be counseled and strictly adhere to recommendations for antibiotic prophylaxis against endocarditis.

Another potential complication of valve implantation is patient-prosthesis mismatch, arising from an undersized (aortic) prosthetic effective orifice area compared with patient body surface area. Inadequate prosthetic valve effective orifice area can lead to elevated transvalvular gradients, resulting in persistent ventricular hypertrophy, impaired ventricular remodeling, and excessive late cardiac events. Patient-prosthesis mismatch is unusual with the excellent hemodynamic performance of current

TABLE 112.4 Anticoagulation Recommendation With Prosthetic Valves

VALVE TYPE	ANTICOAGULATION RECOMMENDATION	DURATION	INDICATION CLASS	
Mechanical	Aspirin[a]	Warfarin (INR goal)		
MVR	+	(3.0)	Long term	I
AVR (+ risk factors)[b]	+	(3.0)	Long term	I

valves, although aortic root or annular enlargement can be safely performed to accommodate a sufficiently sized prosthesis.

Specific Valvular Lesions

Aortic Stenosis

In the developed world, aortic valvular stenosis (AS) is the most common form of valvular heart disease requiring surgical intervention. AS is most often acquired, resulting from degenerative calcific changes to the valvular apparatus that lead to progressive stenosis. Because of the aging population, the prevalence of AS continues to rise, and it is now found in 3% of the population over 75 years old.[1] Most patients requiring surgery for trileaflet AS are aged 60 years or older. The progression of degenerative (calcific) aortic stenosis is now thought to be an actively regulated phenomenon related to atherosclerotic disease, wherein turbulent blood flow at leaflet attachment points induces endothelial injury and leads to lipid accumulation, infiltration of macrophages and T cells, and transformation of cells to an osteoblastic phenotype.[29] It is believed that this process leads to fibrosis and aortic leaflet calcification and may involve the aortic and mitral annuli as well as the mitral leaflets.

Patients less than 60 to 65 years old most often present with aortic stenosis resulting from fibrosis or calcification of a congenitally bicuspid aortic valve, which is susceptible to pathologic change at an earlier age. Bicuspid valves are present in 1% of the population, making this anomaly one of the most prevalent congenital valve lesions, with a 2:1 to 3:1 male-to-female ratio. There is also an association with other lesions, including coarctation, supra- or subvalvular AS, ventricular septal defect, sinus of Valsalva aneurysm, and patent ductus arteriosus. Degenerative disease of bicuspid aortic valves presents about two decades earlier than it does with tricuspid valves, peaking in the fifth and sixth decades of life. Sixty percent of patients over 70 years of age and 40% under 70 years of age with bicuspid valve will require aortic valve replacement to treat stenosis. Increased hemodynamic stresses associated with the abnormally configured bicuspid valve leaflets are thought to accelerate degenerative valve changes in this anomaly. Patients with bicuspid valves can have pure bicuspid pathology with two equal leaflets (Sievers type 0, 6% of bicuspid patients) or with fusion of two of the aortic cusps (Sievers type I), most commonly fusion of the right and left cusps (71% of patients), followed by fusion of the right and noncoronary cusps (15%) and noncoronary and left cusps (3%).[30] Unicuspid valves (Sievers type II, 5% of patients) have congenital fusion of multiple cusps and generally present with stenosis and symptoms at an early age.

Pathophysiology

The normal aortic valve orifice measures 3 to 5 cm^2. Aortic valve stenosis to less than half this size causes hemodynamic obstruction and a transvalvular pressure gradient as the primary pathophysiology of AS. This gradient induces compensatory increased ventricular pressure generated through Frank-Starling mechanisms and concentric LV hypertrophy via parallel replication of sarcomeres as a response to increased myocardial wall tension. Wall tension thereby normalizes according to the law of Laplace, and a compensated state preserving the systolic function of a hypertrophied but nondilated LV may persist for many years.

Two-thirds of patients who progress to severe AS develop myocardial ischemia because of the increased work and, consequently, elevated myocardial oxygen demands of the hypertrophied ventricle. The ventricle must generate increased ejection pressures over prolonged systolic intervals against the increased afterload of the narrowed aortic valve. Myocardial ischemia, particularly in the subendocardial region, is accentuated by the reduction of perfusion gradients during diastolic coronary flow intervals across the hypertrophied, hyperpressurized myocardial wall.

Myocardial hypertrophy can also precipitate ventricular diastolic dysfunction, which typically occurs before the onset of systolic dysfunction. Decreased ventricular compliance leads to increased left ventricular end-diastolic pressure (LVEDP), prolonged LV relaxation time, and shortened diastolic filling time. These increased pressures are transmitted back through the LA and pulmonary circulation, leading to pulmonary congestion. Pulmonary hypertension and right HF may develop in severe cases. Eventually, maximal ventricular hypertrophy is reached, and an adequate pressure gradient can no longer be achieved, resulting in inadequate cardiac outputs and overt systolic LV failure.

Increased LA pressure and consequent LA dilatation also increase the risk for atrial arrhythmias in patients with AS, albeit less commonly than in patients with MV disease. The loss of normal atrial contraction severely compromises filling of the noncompliant ventricle, leading to a precipitous decrease in cardiac output. Reduced forward flow can further increase LVEDP and aggravate the symptoms of HF.

Presyncope and syncope occur with AS related to inadequate cerebral perfusion, typically caused by inadequate forward flow through the restrictive aortic valve. Symptoms are associated with periods of peripheral vasodilatation, such as occurring during exercise or in changing from recumbent to standing positioning, when increased cardiac output is required to maintain peripheral vascular filling.

Diagnosis

Symptoms and signs. Patients with AS will typically remain asymptomatic for an extended time. The onset of symptoms occurs when the valve orifice area decreases to approximately 1 cm^2, which marks a critical point in the natural history of the disease. The classic symptoms of AS typically progress from the appearance of angina and (pre-)syncope to the occurrence of dyspnea associated with HF. Angina is the presenting symptom in 35% of AS patients, whereas syncope is a relatively sporadic event in about 15% of patients. Although HF typically appears late in the course of AS, dyspnea or other HF symptoms are presenting signs in 50% of patients.

Physical examination. The diagnosis of AS based on physical findings is frequently made before the onset of symptoms. The typical finding of AS is a crescendo-decrescendo ejection murmur best heard in the right second intercostal space and along the left sternal border. Radiation to carotid arteries is common. The apical impulse in AS is forceful and slightly enlarged. If HF develops, the apical impulse may become laterally displaced. The characteristic carotid upstroke of AS has a slow rate of rise and a reduced peak *(pulsus parvus et tardus)* and may have an associated thrill.

Diagnostic testing. Nonspecific findings of AS on chest radiography include a boot-shaped heart typical of concentric hypertrophy of the left ventricle, calcification of the valvular cusps, and poststenotic dilatation of the aorta. Roentgenographic signs of HF may ensue. Electrocardiographic changes are similar to those seen for MR.

Echocardiography allows the precise assessment of aortic valve anatomy, calcification, and effective orifice size. Ventricular hypertrophy and function can also be assessed. As with MS, Doppler echo allows measurement of transvalvular pressure gradients and valve area as a derived function (e.g., severe AS: Doppler velocity >4 m/sec = mean aortic valve gradient >40 mm Hg = valve area <1.0 cm^2). Pressure gradients may be decreased in AS patients with low cardiac output, leading to miscalculated (falsely increased) aortic valve areas. This is referred to as *low-flow, low-gradient AS.* Dobutamine may be used during echo to increase cardiac output and assess the true severity of the AS lesion in these patients. Low-flow, low-gradient severe AS with normal LV function can be diagnosed by indexing the valve area and flow rate to the body surface area. In patients with only moderate AS with LV dysfunction, the valve area will increase as flow increases with the addition of dobutamine.

Cardiac catheterization may occasionally be needed to measure pressure gradients when data from noninvasive testing are nondiagnostic. Simultaneous pressure readings can be obtained in such instances with one pressure-measuring port in the body of the left ventricle and a second portion in the proximal aorta. Valvular area may then be determined using the Gorlin formula. Catheterization is important before surgery to assess the presence of coronary artery disease, coexistent in up to 50% of AS patients.

Natural History

Calcific AS is a progressive disease marked by a long, asymptomatic latent period that may vary greatly between individuals. Patients with moderate AS can, however, be expected to undergo a 7–mm Hg increase in mean pressure gradient or a 0.1-cm^2 decrease in valve area annually. Conversely, only about 10% of patients with mild aortic valve sclerosis (aortic velocity <2.5 m/sec) progress to severe AS within 5 years.

Ross and Braunwald's classic 1968 report first described the onset of symptoms as survival indicators in patients with AS (Fig. 112.15).[31] Mean survival after the appearance of angina is about 5 years, less than 3 years after the onset of syncope, and only 1 to 2 years once HF symptoms develop. Sudden death may also occur in symptomatic patients at a rate of 2% per month but appears to be rare ($<1\%$ per year) in asymptomatic patients.[32]

Treatment

Medical management. In general, medical therapy for AS is ineffective. Afterload reduction can lead to severe hypotension with a subsequent decline in cardiac output. Intraaortic balloon pump counterpulsation can improve cardiac output and coronary flow for patients in cardiogenic shock while awaiting surgical intervention, but medical therapy will not reverse the hemodynamic changes consequent to the resultant obstruction to LV output from the stenotic valve.

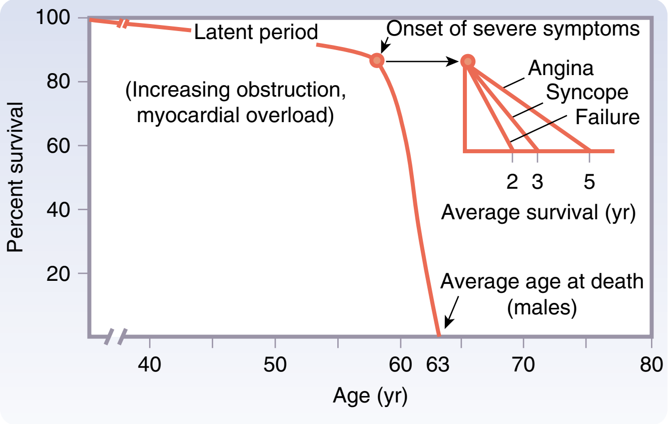

FIGURE 112.15 Symptoms and survival in aortic valvular stenosis. Ross and Braunwald's classic 1968 report first described the onset of symptoms of heart failure, syncope, or angina in patients with aortic valvular stenosis as a marker of impending death. (From Ross J Jr, Braunwald E. Aortic stenosis. *Circulation.* 1968;38:61-67.)

Surgical Treatment

Because the natural history of untreated symptomatic AS is grave, mechanical relief of AS is recommended as a class I indication in all symptomatic patients with evidence of severe high-gradient AS (aortic velocity ≥ 4.0 m/sec or greater or mean pressure gradient ≥ 40 mm Hg) as well those patients with low-flow, low-gradient AS.[10] In addition to history taking, exercise or dobutamine stress echo is useful in eliciting symptoms and/or abnormal physiology (e.g., fall in systolic blood pressure, increase in transvalvular gradient, or decreased exercise tolerance) as a class IIa indicator for surgical intervention. Surgical intervention now also carries a class I indication in the asymptomatic patient with severe AS and evidence of LV dysfunction (left ventricle ejection fraction [LVEF] $<50\%$). A class IIa indication also exists for asymptomatic patients with very severe AS (aortic velocity ≥ 5.0 m/sec or mean pressure gradient ≥ 60 mm Hg) who present low predicted surgical mortality risk ($\leq 4\%$), given that symptoms are expected in 50% of these patients within 2 years and evidence suggesting that overall mortality risk is reduced with early surgery. Patients with severe AS (class I) or moderate AS (class IIb) who are undergoing cardiac surgery for other reasons can be considered for aortic valve replacement as well.

Surgery for AS almost always requires valve replacement, either with a mechanical or tissue valve or with a transcatheter biologic valve. Valve replacement is associated with excellent immediate and long-term outcomes, especially when conducted before the onset of ventricular dysfunction. Aortic valve surgery improves symptoms, increases life expectancy, and often improves or normalizes systolic function, depending on pathophysiologic status of the LV before surgery.

Exposure of the aortic valve is typically obtained via a transverse or "hockey stick" incision of the proximal ascending aorta (Fig. 112.16A). For valve replacement, the native aortic valve cusps are carefully excised to avoid perforation of the aortic wall, and a thorough decalcification of residual annular tissue is performed to improve prosthetic valve fit. After the resected valve orifice is sized (using a plastic avatar), the selected valve prosthesis is typically secured to the valve annulus using circumferentially placed, nonabsorbable, braided horizontal mattress sutures (see Fig. 112.16B). The sutures are tied securely so that there is no perivalvular defect, which would allow a regurgitant leak, and the aortotomy is closed. Homografts or "freestyle" stentless aortic valve homografts may sometimes be used if aortic root replacement is concomitantly required.[33] Repair options for the treatment of AS are limited, and earlier efforts at valve debridement met with poor intermediate-term outcomes with delayed onset of regurgitation, which led to the general abandonment of this technique.

Ross Procedure

The Ross procedure is a complex surgical procedure where the aortic valve or root is replaced with the native pulmonary valve, and the RV outflow tract is reconstructed with a homograft. This procedure may be considered in select young patients under 50 years of age at a Comprehensive Valve Center (class IIb).[10] It is a technically demanding procedure, and at present, the lack of

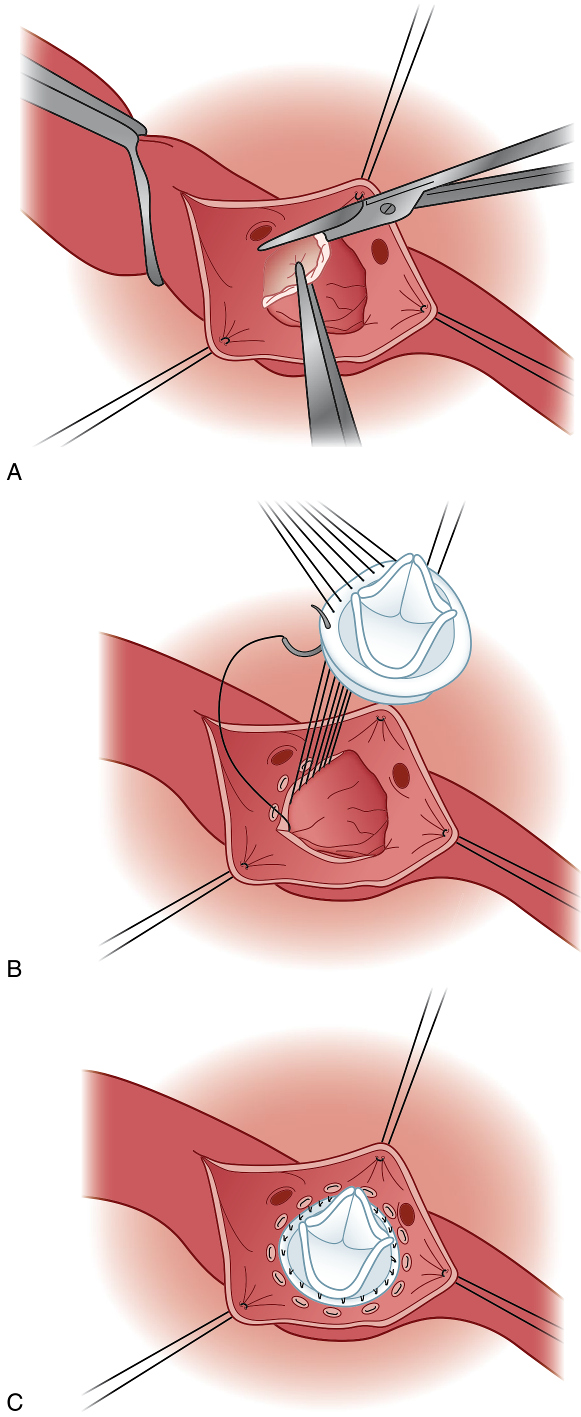

FIGURE 112.16 Aortic valve replacement surgery. Exposure of the aortic valve is typically obtained via a transverse or "hockey stick" incision of the proximal ascending aorta. After aortic valve excision (A), pledgeted horizontal mattress sutures are placed circumferentially into the valve annulus and then into the cloth sewing ring of the prosthesis (B). The prosthesis is then lowered into position, and the sutures are tied (C).

standardization of the operation may compromise its long-term durability. Specifically, maneuvers are being tested to reduce late dilation of the pulmonary autograft, stabilize a large native aortic annulus, and reduce long-term moderate to severe pulmonary homograft stenosis.

Transcatheter Aortic Valve Replacement

Transcatheter aortic valve replacement (TAVR) has become standard therapy to implant a bioprosthetic aortic valve in the aortic annulus through catheter technology without removal of the native aortic valve. It is mainly performed without the use of cardiopulmonary bypass. Currently available valves are generally grouped into balloon-expandable and self-expandable valves. (Fig. 112.17). This technology has rapidly evolved since its introduction in 2002 by Alain Cribier and colleagues to treat an inoperable patient with severe AS.[34,35] TAVR is an increasingly prevalent alternative to surgical aortic valve replacement (SAVR) and has replaced SAVR as the most common procedure to treat isolated AS.

Compelling evidence of the efficacy of TAVR was first provided by the Placement of AoRtic TraNscathetER Valves (PARTNER) trial, the world's first randomized study of this procedure.[36,37] These procedures were initially conducted in patients considered inoperable, and they were deemed to be superior to the standard therapy of balloon valvuloplasty in this cohort. Based on PARTNER and subsequent trials demonstrating that outcomes from TAVR were at least noninferior to SAVR, the FDA granted approval for TAVR in 2011 for prohibitive risk (STS >50% 30-day mortality or major morbidity) patients and in 2012 for high-risk (Society of Thoracic Surgeons [STS] predicted mortality >10% or ≥2 indices of frailty or >1 compromised major organ system) patients with a predicted postprocedural survival greater than 12 months. A critical component of these FDA approvals was the advent of the Heart Team, consisting of both cardiologists and cardiac surgeons, in evaluation and treatment of TAVR patients—a practice that has expanded to other cardiac surgery decision-making processes.

Expansion of indication to intermediate-risk patients (STS >4%–8% mortality)[38,39] and low-risk patients (STS ≤4% mortality)[40,41] followed in 2016 and 2019, respectively. Improved overall outcomes, stroke rates, and vascular complication rates in these second-generation trials have been generated through innovation of smaller-caliber catheters, better preprocedural planning with dedicated TAVR-protocol computed tomography (CT) review, improved patient selection, and deployment strategies. Complications such as complete heart block and paravalvular regurgitation are higher after TAVR than SAVR, and these

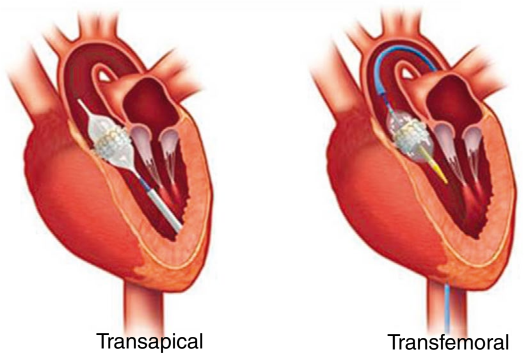

FIGURE 112.17 Transcatheter aortic valve replacement (TAVR). TAVR couples balloon aortic valvuloplasty with implantation of an expandable bioprosthesis delivered and expanded into the aortic annulus using catheter technology. (From Pick A. Surgeon Q&A: "What Determines the Transfemoral or Transapical Approach for TAVR?" Asks Denise. September 18, 2013. http://www.heart-valve-surgery.com/heart-surgery-blog/2013/09/18/tavr-transfemoral-transapical-approaches/. Accessed August 11, 2020.)

complications have been linked to higher long-term mortality. Other unanticipated complications also remain a concern, including increased valve thrombosis rates in TAVR versus SAVR valves. Clinical leaflet thrombosis, although rare at 0.5% of TAVR patients per year, may lead to elevated gradient and recurrent symptoms. Subclinical thrombosis more commonly affects up to 15% of TAVR patients.[42] Leaflet thrombosis may manifest as hypoattenuated leaflet thickening with or without restricted leaflet motion. Although the role of oral anticoagulation has been studied to decrease rates of subclinical thrombosis, this has not led to clear clinical benefits at this stage.

Aortic Regurgitation or Insufficiency

Aortic regurgitation (AR) or AI may be caused by myxomatous disease leading to thinning, enlargement, perforation, and/or prolapse of the aortic valve cusps themselves. AI may also be caused by chronic or acute dilatation of the aortic root, which prevents proper aortic valve coaptation by increasing intravalvular closing distances. Root enlargement is typically caused by hypertension and/or connective tissue disorders such as cystic medial necrosis, Marfan syndrome, Ehlers-Danlos syndrome, and Loeys-Dietz syndrome, either directly or as a result of acute or chronic aortic dissection.

Importantly, (Mendelian) inheritance of a bicuspid aortic valve anomaly is also associated with dilation of the proximal ascending aorta in up to 50% of patients, which can lead to bicuspid-related AI.[43] This association is hypothesized to be due to a currently unidentified common genetic defect causing abnormalities in aortic wall elasticity. AI resulting from bicuspid valve–related root enlargement typically develops at a much younger age than AS that develops from accelerated degeneration.

Less common causes of aortic root enlargement and/or aortic dissection include giant cell aortitis (most often in elderly females), Takayasu aortitis (more commonly affects the aortic arch branch vessels), and syphilitic aortitis (mostly of historical interest only).

Pathophysiology

The aortic valve is dependent on the coordinated function of a complex and dynamic anatomy to preserve its competency. This apparatus includes the aortic valve cusps, annulus, sinuses of Valsalva, and the sinotubular junction above the sinuses. AI may be induced by pathologic processes that may alter any one or more of these components and/or their anatomic relationships with each other.

Acute AI, usually the consequence of endocarditis or aortic dissection, produces sudden increases in left ventricular end-diastolic volume (LVEDV) caused by acute regurgitant flow into a relatively small, nonadapted, noncompliant ventricle. Even greater increases in LVEDP may lead to equalization of systemic and ventricular pressure that can temporarily curtail increased regurgitation. Transmission of increased LVEDP into the pulmonary circuit, however, may produce fulminant pulmonary edema, especially in the setting of coexisting MR aggravated by sudden increases in LV dimensions. Consequently, an increase in LV wall tension leads to myocardial ischemia, (exacerbated if aortic dissection extends to the coronary ostia), hemodynamic collapse, or sudden death.

Chronic AI, like chronic MR, is an insidious process that triggers compensatory mechanisms, including LV enlargement and hypertrophy, that help maintain net forward stroke volume and decrease wall tension. At first, increases in LV filling caused by mild or moderate regurgitant flow lead to increases in LVEDV and improvement in LV contractility along the Frank-Starling curve. Increases in afterload and wall stress caused by increases in LVEDV likewise lead to eccentric ventricular hypertrophy characterized by sarcomere replication in series and elongation of myofibers. This hypertrophy tends to preserve ventricular compliance and minimize increases in LVEDP while still decreasing wall tension. Increases in heart rate and decreases in peripheral vascular resistance that reduce diastolic filling time and decrease afterload also act to decrease regurgitant flow. Because of these mechanisms, patients with chronic AI often remain well compensated for many years.

Ultimately, the sum effect of myocardial hypertrophy and LV enlargement in AI patients is a dramatically enlarged heart known as *cor bovinum,* characterized by the largest EDV and mass of any form of heart disease. AI ventricles can ultimately weigh as much as three times normal and have a capacitance of over 200 mL (~4× normal) to accommodate massive regurgitant volumes. Progressive changes in LV dynamics eventually exhaust preload reserve and overwhelm compensation mechanisms, and increased LVEDV and LVEDP lead to ventricular dilatation, increased wall tension, and increased myocardial oxygen demand. Decreased systemic diastolic pressure and increased intramyocardial wall tension decrease coronary perfusion and further exacerbate myocardial ischemia. Ultimately, ischemia may lead to myocardial fibrosis and cardiomyopathy. When the ventricle can no longer maintain adequate forward flow, overt HF ensues.

Diagnosis

Symptoms and signs. Severe acute AI may be difficult to recognize clinically, although acute AI patients may present with dyspnea, hemodynamic instability, or shock. Frequently, symptoms reflecting the underlying cause of the AI, such as fever from endocarditis or chest pain from aortic dissection, may mask AI symptoms and obscure a correct diagnosis. Chronic AI typically presents with HF symptomatology when decompensation develops, although severe chronic AI patients may also present with angina or palpitations during stress or exertion.

Physical examination. Acute AI may yield few, if any, diagnostic signs other than those of fulminant HF and/or hemodynamic collapse. In comparison, chronic AI typically offers many physical findings, primarily related to the increases in stroke volume and pulse pressure resulting from regurgitant flow back into the ventricle in AI patients. These signs include peripheral pulses that rise abruptly with a rapid collapse (water-hammer pulse), a bounding carotid pulse (Corrigan pulse), head bobbing with each heartbeat (de Musset sign), pulsation of the uvula (Müller sign), a "pistol shot" auscultated with compression of the femoral artery (Traube sign), and capillary pulsations seen with fingernail compression using a glass slide (Quincke sign).

Cardiac examination typically reveals an apical impulse that is diffuse, hyperdynamic, and displaced inferiorly and laterally. It may be associated with a systolic thrill at the base of the heart, suprasternal notch, and carotid arteries as a result of high stroke volume. Auscultation reveals a high-frequency, blowing, decrescendo diastolic murmur best heard with the diaphragm at the left sternal border with the patient sitting up, leaning forward, and at end-exhalation. The murmur is increased by maneuvers such as squatting or handgrip, which increase diastolic pressure. The examiner may appreciate a mid- and late-diastolic apical rumble (Austin-Flint murmur), which is thought to be secondary to vibration of the anterior mitral leaflet caused by a posteriorly directed AI jet. The second heart sound may be soft or absent, and a third heart sound may be present.

Diagnostic testing. Chest radiography in patients with acute AI may reveal only pulmonary edema, and electrocardiography (ECG) may reveal evidence of LV strain, but echocardiography may be the only test useful in diagnosing this condition. With chronic AI, chest radiography typically shows a significantly enlarged cardiac silhouette. The ascending aorta may be enlarged if AI is a result of an aortic aneurysm. ECG will typically show signs of increased LV mass, notably left axis deviation and increased QRS amplitude with strain patterns and conduction abnormalities.

Echocardiography allows the comprehensive evaluation of aortic apparatus abnormalities, LV size and compliance, and the character and magnitude of the regurgitant jet. Severe AI is diagnosed by a jet width ≥65% of the LV outflow tract, vena contracta >0.6 cm, regurgitant fraction (RF) ≥50%, regurgitant volume ≥60 mL/beat, or an effective regurgitant orifice (ERO) area ≥0.3 cm^2. Cardiac magnetic resonance imaging (MRI) can also be used to quantify severity more accurately. RF >33% and LVEDV >246 mL increase the likelihood of progression of disease and valvular intervention within 3 years, whereas RF ≤33% rarely progresses.[44]

Natural History

Although acute AI may lead to the sudden onset of HF and/or hemodynamic collapse, patients with chronic AI remain asymptomatic for years with compensated LV function. The combined likelihood of onset of adverse events for such patients (LV dysfunction, onset of symptoms, or death) is less than 5% per year. Overall, the freedom from ventricular dysfunction or death in asymptomatic patients is about 75% at 5 years and 60% at 10 years.[45] Once the LV end-systolic diameter is ≥50 mm, adverse event rates increase to about 20% per year, and once symptoms develop in AI patients, mortality rates rise to over 10% per year.[10,11,45]

Treatment

Medical management. Medical therapy should be considered only as a temporizing measure for patients with acute severe AI and acute volume overload, hypotension, and/or pulmonary edema because they will require emergent surgery. In this scenario, vasodilators and inotropes may be valuable in augmenting forward flow and reducing LVEDP. β-blockers used for aortic dissection should be employed with great caution in other causes of acute AI because they block compensatory tachycardia and could cause a significant drop in blood pressure. Importantly, intraaortic balloon pump is contraindicated in severe AI because it will worsen regurgitation and forward output.

Patients with chronic severe AI may benefit from medical management, with the primary goal of reducing systolic hypertension, therefore reducing wall stress and improving ventricular function. Vasodilating drugs may improve hemodynamic abnormalities and forward flow, but their effect in favorably prolonging the asymptomatic period in patients with chronic severe AI and normal ventricular function is uncertain.

Surgical Treatment

Urgent or emergent surgical intervention to repair or replace the aortic valve and address underlying pathologic mechanisms is nearly always indicated in patients with acute severe AI (e.g., for endocarditis, aortic dissection). Surgery is also indicated (class I) for symptomatic patients with severe chronic AI.[10] Importantly, based on improved current understanding of the natural history of chronic AI, aortic valve surgery is now a class I indication for asymptomatic chronic severe AI patients with LV systolic dysfunction (LVEF <50%). It should also be considered for asymptomatic severe AI with LVEF ≥50% with severe LV dilation (LVESD >50 mm or indexed LVESD >25 mm/m^2) as a class IIa indication or as class IIb indication for progressive severe LV dilation (LV end-diastolic diameter >65 mm).[10]

Valve replacement with mechanical or biologic prostheses has yielded excellent results in correcting isolated AI (see Table 112.5); however, over the past two decades, increasing numbers of centers are employing repair strategies in selected patients. For patients with aortic root disease, these procedures are typically combined with root repair or replacement and coronary reimplantation, as discussed elsewhere in this text.

Percutaneous transcatheter valve therapies to address AI are still under clinical investigation and are not yet FDA approved. In select patients, AI may be treated by the Ross procedure. Durable results with this technically demanding procedure have been demonstrated in highly experienced centers, especially for younger patients (<30 years of age) and in very young patients where significant growth is anticipated.

Aortic valve repair may be an option for selected patients with AI or a normally functioning aortic valve associated with an aortic root or ascending aortic aneurysm. When AI is secondary to dilation of the aortic root or ascending aorta, valve-sparing operations that stabilize the annulus and remodel the sinotubular junction can be very effective. Valve-sparing root replacement, commonly known as the "David" procedure after Dr. Tirone David, the pioneer of this operation, is a complex but highly successful procedure involving reimplantation of the native valve inside a Dacron graft.[46,47]

Mitral Stenosis

Pathophysiology

There is typically no pressure gradient across a normally sized MV (4–6 cm^2 cross-sectional area), and "upstream" LA pressure is typically less than 10 to 15 mm Hg. As the MV orifice narrows to a cross-sectional area of 2 to 2.5 cm^2 (mild MS), resistance to flow leads to increased LA blood volume "pooling." Increased LA pressure generated by Frank-Starling mechanics maintains adequate diastolic flow across the resistive valve orifice.

When progressive MS leads to a transvalvular gradient of greater than 5 to 10 mm Hg, typically corresponding to a valve orifice of ≤1.5 cm^2, MS is classified as "severe." The resultant increase in LA pressure is transmitted upstream to the pulmonary veins, capillaries, and arteries. At an LA pressure of 25 mm Hg, pulmonary edema typically develops, with prolonged arterial vasoconstriction and vascular remodeling eventually leading to reversible at first, but then ultimately fixed, pulmonary hypertension with chronically increased pulmonary pressure. Elevated pulmonary arterial systolic pressure (PASP) ≥60 mm Hg imparts significant RV afterload and will ultimately lead to RV dilatation, TR, and RV failure. MS spares LV function in two-thirds of cases, with normal or less-than-normal LV chamber hemodynamics in 85% of cases and impaired output primarily resulting from restricted LV inflow.

Any increase in cardiac output, as with exercise, will lead to an increase in mitral transvalvular pressure gradients according to the law of Poiseuille: flow α Δpressure gradient/resistance. At a given cardiac output, decreased diastolic filling time caused by increased heart rates, such as with exercise or the onset of atrial fibrillation, will also cause increased transvalvular gradient because more flow must occur per unit time.

Chronically increased transmitral pressure gradients caused by MS typically lead to atrial hypertrophy and dilatation. Associated LA fibrosis and disorganization of the atrial muscle fibers cause abnormal atrial conduction velocities and refractory times. Increased automaticity, ectopic foci, and reentry circuits eventually lead to supraventricular tachyarrhythmias in nearly 40% of patients. Loss of the "kick" generated by normal atrial contraction, responsible for 30% of ventricular filling, results in a 20% decrease in cardiac output. Atrial pressure then must increase to facilitate sufficient ventricular loading. Atrial fibrillation consequently causes increased diastolic pressures and volume overload, potentially leading to worsening congestion.

Mitral stenosis is commonly caused by RHD in underdeveloped countries, and RHD most commonly involves the MV. It is highly uncommon to have valvular RHD without mitral involvement. In the developed world, mitral annular calcification (MAC) and calcification of the MV leaflets are quite common, especially with advanced age. MAC is usually a finding, not a symptom, because it generally has no effect on MV function. MAC is a common degenerative change found in older patients that is typically without functional sequelae. The prevalence of MAC is 5% to 10% in those 60 years of age but increases to nearly 50% in those over 70 years of age.[48] MAC can, however, on occasion produce MR by reducing annulus pliability and systolic contraction, thus preventing appropriate leaflet coaptation. Less frequently, MAC disorders manifest through a more widespread degenerative pathology. MAC may be associated with similar changes involving the aortic valve or coronary atherosclerosis, in which case its presence portends a poor long-term prognosis in these patients.

Although MAC often coexists with aortic valve calcification and coronary atherosclerosis, its pathogenesis is distinct. Presumed mechanisms for MAC include molecular injury with abnormal collagen matrix serving as the substrate for lipid deposition and bone formation promulgated by inflammation and dysregulation of calcium-phosphate handling. When MAC affects MV function, diffuse calcification of both leaflets can cause mitral stenosis as a result of leaflet retraction and calcific distortion of proper motion of the mitral subvalvular apparatus. Occasionally, annular calcification will extend only to the posterior leaflet, in which case it can cause MR as a result of restricted leaflet motion. Degenerative calcific disease that is nonrheumatic in origin in the most common cause of MS in older patients. Other rare causes of MS include endocarditis and congenital anomalies such as parachute MV and as a component of Shone complex, which is associated with supramitral rings.

Diagnosis

Symptoms and signs. MS patients may remain asymptomatic for many years. As valvular stenosis gradually worsens, however, symptoms characteristic of low cardiac output and pulmonary venous congestion eventually develop, including fatigue, dyspnea, and orthopnea. Ultimately, peripheral edema and other congestive symptoms caused by volume overload and right HF ensue. Increased heart rate caused by atrial fibrillation or supraventricular tachycardia, exercise, or other factors may exacerbate symptomatology.

Patients with MS who develop atrial fibrillation may complain of palpitations and symptomatic tachycardia. More ominously, thromboembolization will occur in 20% of patients with MS and may be its first symptom in 10% of cases, presenting as stroke, myocardial ischemia or infarction, renal infarction, and gut or limb ischemia. Half of all thromboembolic events will involve the cerebral circulation. Thromboembolism associated with atrial fibrillation is generally a result of stasis of blood in the LA appendage when normal pump function (atrial contraction) is impaired. Rarely, a large, pedunculated atrial thrombus may form and obstruct the valve inlet, resulting in hemodynamic collapse and sudden death. Pulmonary venous congestion may induce hemoptysis from sudden rupture of a dilated bronchial vein. RV failure and TR can cause abdominal pain and swelling from hepatomegaly, ascites, and, often, peripheral edema.

Physical examination. The characteristic physical finding of MS is a low-pitched, rumbling diastolic murmur that is best heard at the apex with the patient in the left lateral decubitus position. In patients who are in sinus rhythm, the murmur increases in intensity during late diastole (known as *presystolic accentuation*) because of the increased flow across the stenotic valve with atrial contraction. A high-pitched "opening snap" or an accentuated first heart sound caused by forceful opening or closing, respectively, of an inflexible but still mobile mitral leaflet may be heard with early MS. The Graham-Steell murmur, an early blowing diastolic murmur of functional pulmonary regurgitation, is caused by pulmonary hypertension and right-sided overload from MS.

Advanced MS is typically associated with rales developing with the onset of pulmonary edema. As RV failure develops, an RV heave, jugular venous distention, hepatomegaly, ascites, and lower extremity edema may be found.

Diagnostic testing. The classic appreciable changes of MS discernable by routine chest radiography include evidence of an enlarged LA, seen as a straightening of the left cardiac border; a double shadow in the cardiac silhouette; or an elevated left main stem bronchus. Prominent pulmonary vessels may also be appreciated. If stenosis is severe, congested pulmonary lymphatics in the lower lung fields may be present as horizontal linear opacities, known as *Kerley B lines.* MV calcification may also be visible. Stigmata of HF, such as opacification of the lung fields and pleural effusions, may follow. The changes in chest radiography, though, are mostly of historical interest because patients generally present before developing the massive secondary consequences of long-term disease, which was more the case before the advent of adequate medical and surgical therapeutic options.

The ECG of MS patients is often grossly normal, although 90% of patients will demonstrate evidence of LA enlargement as a widened, notched P wave (p mitrale). Atrial arrhythmias may also be appreciated if present. With advanced MS, RV hypertrophy may be associated with right-axis deviation.

Echocardiography, as with other valve lesions, is the primary diagnostic method to determine the presence and severity of MS and associated abnormalities. Commissural fusion, leaflet immobility, and leaflet and annular or subvalvular thickening and calcification can be well assessed by transthoracic and especially by transesophageal echocardiography (TEE). Three-dimensional (3D) echocardiography provides further definition of valve morphology and function.

Doppler echocardiography has largely replaced cardiac catheterization in accurately assessing the hemodynamic parameters of MS and other valve lesions. Doppler blood velocity measurement allows mean and peak transvalvular mitral pressure gradient determination as a function of the simplified Bernoulli equation: $p = 4v^2$, where v equals the velocity of blood crossing the valve orifice. Orifice area can be measured by planimetry (tracing the valve-opening orifice on a still echocardiographic image) or as a derivative of velocity measurements based on continuity equations. MV area can also be determined based on the pressure half-time, the time in which the transvalvular velocity decreases by half. Pressure half-time will become prolonged with increasing severity of stenosis.

Natural History

Ten-year patient survival is greater than 80% in the asymptomatic patient with MS, and interventional treatment is consequently not recommended in this setting. In comparison, 10-year survival for symptomatic patients with severe MS who forgo intervention is less than 15%, and mean survival is less than 3 years in patients with MS and severe pulmonary hypertension.

Treatment

Medical management. Medical management of patients with symptomatic MS includes the use of diuretics to reduce LA pressure and vascular congestion. β-blockers and calcium channel-blocking agents are recommended to provide heart rate control and help maintain sinus rhythm. Anticoagulation therapy is recommended via CHADS$_2$ and the updated CHADS$_2$-VASc (modification to better assess low-risk patients) scoring systems in patients with atrial fibrillation (Table 112.6) and in patients without atrial fibrillation but who have suffered a prior embolic event or have a documented LA thrombus. Use of anticoagulation therapy must be tempered against the risk of major bleeding, which can now be calculated using the Hypertension, Abnormal renal/liver function, Stroke, Bleeding history or predisposition, Labile INR, Elderly [>65 years], Drugs/alcohol concomitantly (HAS-BLED) scoring system developed in 2010 from data in the Euro Heart Survey to assess 1-year risk of major bleeding in patients taking anticoagulants with atrial fibrillation.[49]

TABLE 112.6 CHADS$_2$ and CHADS$_2$-VASc Score for Atrial Fibrillation Stroke Risk and Recommended Anticoagulation

	CHADS$_2$ SCORE	POINTS[a]	CHADS$_2$-VASc SCORE	POINTS[a]
C	Congestive heart failure	1	Congestive heart failure	1
H	Hypertension	1	Hypertension	1
A	Age ≥75 years	1	Age ≥75 years	2
D	Diabetes mellitus	1	Diabetes mellitus	1
S	Prior stroke, TIA, or thromboembolism	2	Prior stroke, TIA, or thromboembolism	2
V			Vascular disease	1
A			Age 65–74 years	1
Sc			Sex category (female)	1

[a] Points for each risk factor are additive.

CHADS$_2$: Score of 0, low risk; 1, moderate risk; 2–6, high risk.

CHADS$_2$-VASc: Score of 0 (male) or 1 (female), low risk; 1, moderate risk (male); 2–9, high risk.

Recommended therapy for moderate or high risk is typically oral anticoagulant, with well-controlled vitamin K antagonist (VKA; e.g., warfarin with time in therapeutic range >70%) or a non-VKA oral anticoagulant (NOAC; e.g., dabigatran, rivaroxaban, edoxaban, or apixaban).

TIA, Transient ischemic attack.

Surgical Treatment

Early intervention is associated with improved long-term survival for patients with MS compared with patients in whom intervention is delayed until the development of symptomatology. Five-year survival is 62% for New York Heart Association (NHYA) class III patients and 15% for class IV patients.[49,50] The current American Heart Association/American College of Cardiology (AHA/ACC) guidelines accordingly recommend intervention for patients with symptomatic severe (valve orifice area <1.5 cm^2) or asymptomatic very severe (valve orifice area <1 cm^2) mitral stenosis.[10] Additionally, surgery is recommended for patients with moderate or severe MS undergoing cardiac surgery for other reasons and for patients with severe MS who have recurrent embolic events while on anticoagulation (with LA excision recommended). Options for mechanical intervention include percutaneous mitral balloon commissurotomy, open mitral commissurotomy and surgical repair, and replacement of the MV.

Percutaneous Balloon Mitral Commissurotomy

Percutaneous balloon mitral commissurotomy (PBMC) is an endovascular procedure first reported by Inoue and colleagues in 1984. It uses a balloon catheter advanced into the left atrium, via a transseptal puncture or retrograde transaortic delivery, to dilate a stenotic MV. Based on compelling safety and efficacy data, PBMC has largely replaced surgical interventions in appropriately selected patients based on (Wilkins) echocardiographic criteria (Table 112.7). In general, PBMC is indicated by the presence of mobile, noncalcified, thin valves with minimal fusion, scarring, or calcification of the subvalvular apparatus and the absence of moderate to severe MR or an LA thrombus. PBMC is associated with a mortality risk of 0.5% and a less than 10% risk of cardiac or vascular complications, embolization, or creation of severe MR. Successful PBMC, defined as a postdilation valve area of more than 1.5 cm^2 with MR grade less than 2/4, is achieved in over 80% of patients. Although reintervention is often required, over half of patients can expect to remain free from surgery at 20 years.[51] Success rates and durability of repair, however, diminish substantially with each subsequent reintervention.

For open surgery, the MV is typically exposed through a left atriotomy, made anterior to the pulmonary veins (Fig. 112.18A). A right atriotomy and incision through the atrial septum also provide excellent exposure to the MV. Even greater exposure can be provided by a "superior septal" approach joining the right atrial and septostomy incisions onto the dome of the left atrium, but this approach requires more extensive closure and has the potential for sinus node dysfunction and complete heart block.

Open mitral commissurotomy is the primary form of surgical repair of MS and is limited to use for patients in whom intervention is needed but PBMC is contraindicated or those who have failed previous percutaneous intervention. Open mitral commissurotomy requires use of cardiopulmonary bypass and involves division of fused commissures, mobilization of scarred chordae, and ligation of the LA appendage. The mortality rate for open commissurotomy is less than 2%, and the 10-year rate of freedom from reoperation after open mitral commissurotomy is approximately 90%.[52,53] This procedure is rarely performed in the United States and other developed countries.

MV replacement is the most commonly employed surgical management of MS. Regardless of whether a mechanical or tissue valve is employed, there is well-documented evidence that preservation of the subvalvular apparatus is critical for the maintenance of optimal LV geometry and function and improved 30-day and

TABLE 112.7 Wilkins Score for Assessing Appropriateness of Percutaneous Balloon Mitral Commissurotomy

GRADE	MOBILITY	THICKENING	CALCIFICATION	SUBVALVULAR THICKENING
1	Highly mobile valve with only leaflet tips restricted	Leaflets near normal in thickness (4–5 mm)	A single area of increased echocardiographic brightness	Minimal thickening just below the mitral leaflets
2	Leaflet mid- and base portions have normal mobility	Midleaflets normal, considerable thickening of margins (5–8 mm)	Scattered areas of brightness confined to leaflet margins	Thickening of chordal structures extending to one-third of the chordal length
3	Valve continues to move forward in diastole, mainly from the base	Thickening extending through the entire leaflet (5–8 mm)	Brightness extending into the midportions of the leaflets	Thickening extended to distal third of the chords
4	No or minimal forward movement of the leaflets in diastole	Considerable thickening of all leaflet tissue (>8–10 mm)	Extensive brightness throughout much of the leaflet tissue	Extensive thickening and shortening of all chordal structures extending down to the papillary muscles

Sum of the four items ranges between 4 and 16. With a score of 8 or less, percutaneous balloon mitral valvuloplasty is likely to be successful. If the score is more than 8, surgery is recommended.

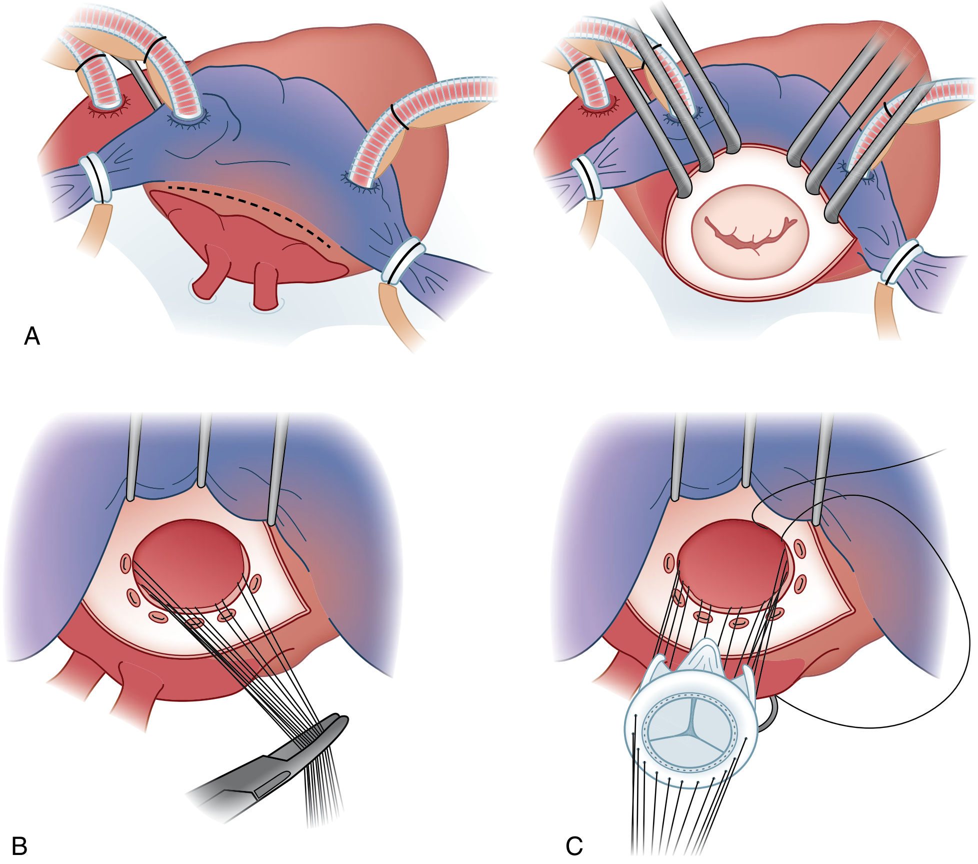

FIGURE 112.18 Mitral valve replacement surgery. (A) The mitral valve is typically exposed through a left lateral atriotomy made just anterior to the pulmonary veins. (B) After partial excision of the native valve, pledgeted horizontal mattress sutures are placed circumferentially into the valve annulus and then into the cloth sewing ring of the prosthesis. (C) Valve lowered into position and sutures securely tied. (From Glower DD. Surgical approaches to mitral regurgitation. *J Am Coll Cardiol.* 2012;60:1315-1322.)

long-term survival.[54,55] If MAC is present or the etiology is calcific disease rather than rheumatic disease, surgery can be more risky. Perivalvular leak resulting from poor sealing of the sewing cuff to the calcified annulus can occur. The most dreaded complication is AV groove disruption resulting from cracking of the calcium in this region. Fatal bleeding can result.

Minimal valve leaflet resection (portion of the anterior leaflet) is currently preferred for MV replacement, making best efforts to preserve the chordae and subvalvular apparatus in continuity with the valve annulus. If the chordae or leaflets are severely calcified or fibrotic, resection may be required to facilitate implantation of an adequately sided valve prosthesis without perivalvular leak. After the resected valve orifice is sized (using a plastic avatar), the selected valve prosthesis is typically secured to the valve annulus using circumferentially placed, nonabsorbable, braided horizontal mattress sutures (see Fig. 112.18B). The sutures are tied securely so that there is no perivalvular defect, and the atriotomy is closed after de-airing of the heart (see Fig. 112.18C).

Mitral Regurgitation

MR is the most frequent form of valve dysfunction and is the second most common type of valvular heart disease requiring surgical intervention. The diagnosis and treatment of MR were greatly facilitated by the work of Carpentier, who, in innovating surgical approaches to repair the MV, also described a functional classification of MR based on abnormal patterns of leaflet motion (Table 112.8).[2] Degenerative changes to the MV apparatus, with leaflet prolapse or elongation/rupture of the chordae tendineae, are the most common causes of MR and can present at any adult age, mostly past the third or fourth decade (see Table 112.1). Surgical intervention for MR is primarily reserved for treatment of degenerative disease. Open surgical intervention for ischemic disease and for functional MR resulting from ventricular cardiomyopathy has diminished dramatically since the introduction of TEER. Endocarditis remains a consistent indication for MV surgery in 2% to 5% of patients.

A wide variety of connective tissue diseases may lead to degenerative disease of the MV, typically causing annular dilation without leaflet abnormalities (Carpentier type I lesion) and/or leaflet or subvalvular deformations resulting in excessive leaflet motion (Carpentier type II lesion). The most prevalent of these diseases is Marfan syndrome. *Myxomatous disease* describes a common pathologic end point of these degenerative diseases, which typically presents as MR in the third or fourth decade of life. This process is characterized by glycosaminoglycan infiltration of the valve leaflets, thickening of the spongiosa, and separation of collagen bundles in the fibrosa.

Myxomatous disease of the MV typically leads to redundant, "billowing" valve leaflets; annular dilatation; and/or chordae elongation with resulting abnormal systolic leaflet prolapse into the atrium. This syndrome typically occurs in young females without obvious connective tissue disease and is known as *Barlow disease* after the clear identification in 1963 of the etiology of this "click-murmur syndrome" by John Barlow in South Africa.[56] Myxomatous disease most commonly manifests as mitral disease, but it may also present as aortic or tricuspid valve pathology.

Fibroelastic deficiency syndrome represents a spectrum of myxomatous MV disease, as clearly described by David Adams from Mount Sinai in New York.[56] Fibroelastic deficiency generally involves myxomatous change of a single segment of the MV, most commonly the posterior leaflet, characterized by thinned leaflets with rupture of a chord without excessive leaflet tissue. Prolapse or flail of the middle posterior leaflet cusp (P2) as a result of chordae rupture is the most common manifestation of fibroelastic deficiency syndrome. Fibroelastic deficiency+ (plus) is fibroelastic deficiency with excessive leaflet tissue in a single segment that will need to be resected to correct the pathologic change. Forme fruste presents with excessive leaflet tissue in multiple segments, generally multiple segments of the posterior leaflet. Barlow disease is the diffuse expression of fibroelastic deficiency with involvement of multiple segments of both leaflets.

Coronary ischemia causing rupture of a papillary muscle or acute myocardial infarction, particularly in the inferior distribution, can also lead to significant MR. This primarily affects the posteromedial papillary muscle, which has a single blood supply from the terminal branch of the posterior descending coronary artery, whereas the anterolateral papillary muscle receives dual blood supply from the left anterior descending and circumflex arteries.

In contrast to the causes of primary MR noted earlier, secondary or "functional" MR is not caused by abnormalities of the valve itself but rather by distortion of the subvalvular apparatus and ventricle. Typically, functional MR is a result of myocardial ischemic events and/or cardiomyopathy-induced ventricular dilatation. Symmetric dilation of the ventricle causes the mitral annulus to dilate, resulting in malcoaptation of the leaflets and central regurgitation during diastole. Asymmetric dilation of the ventricle, often from ischemia, results in outward (lateral) and apical

TABLE 112.8 **Carpentier Classification of Mitral Valve Regurgitation**

CARPENTIER CLASSIFICATION	DYSFUNCTION	LESIONS	ETIOLOGY
Type I	Normal leaflet motion	Annular dilatation Leaflet perforation/tear	Dilated cardiomyopathy Endocarditis
Type II	Excessive leaflet motion (prolapse)	Elongation/rupture of chordae Elongation/rupture of papillary muscle	Degenerative valve disease Fibroelastic deficiency Barlow disease Marfan disease Rheumatic (acute) Endocarditis Trauma Ischemic cardiomyopathy
Type IIIa	Restricted leaflet motion (diastole and systole)	Leaflet thickening/retraction Leaflet calcification Chordal thickening/retraction/fusion Commissural fusion	Rheumatic (chronic) Carcinoid heart disease
Type IIIb	Restricted leaflet motion (systole)	Left ventricular dilatation/aneurysm Papillary muscle displacement Chordae tethering	Ischemic/dilated cardiomyopathy

From Carpentier A. Cardiac valve surgery—the "French correction." *J Thorac Cardiovasc Surg*. 1983;86:323-337.

(inferior) displacement of the posteromedial papillary muscle, causing tethering of the valve leaflets and loss of central coaptation (Carpentier type IIIb lesion). If dyskinesis of the basal inferior wall coexists, replacement of the valve is generally necessary to eliminate regurgitation.

Other acquired forms of MR include those that limit systolic motion of the mitral leaflets (Carpentier IIIa lesion with restricted leaflet most commonly calcific or rheumatic) and restricted motion of the posterior leaflet resulting from ischemic change in the posterior LV wall (Carpentier IIIb lesion). Congenital anomalies such as cleft leaflets and AV canal/endocardial cushion defects also cause MR.

Pathophysiology

Pathologic changes to any component of the MV apparatus may cause improper systolic coaptation between the anterior and posterior mitral leaflets, with subsequent valvular regurgitation. MR is subdivided into primary and secondary MR, which are distinct in their pathophysiology, natural history, and treatment approach. Primary MR, classified as type I (normal leaflet motion with annular dilatation) or II (abnormal leaflet motion) in the Carpentier classification (see Table 112.8), is secondary to pathologies affecting the structure of the MV apparatus, specifically the leaflets, chordae, and annulus. In contrast, secondary or functional MR, classified as Carpentier type IIIb, is secondary to LV dysfunction and dilation, primarily resulting from ischemic cardiomyopathy with restricted posterior leaflet motion. The severity of MR is dependent on the size of the mitral orifice, the pressure gradient between the LA and LV, and the systemic afterload. Because LV pressure exceeds LA pressure well before it exceeds systemic pressure, MV incompetency may allow a significant amount of regurgitant volume (up to one-half of the ventricular preload) into the LA well before the opening of the aortic valve and forward flow into the aorta.

In the acute phase of MR, retrograde flow into a small, low-compliance receiving LA chamber may be poorly tolerated, and high atrial pressures may be transmitted into the pulmonary vasculature. Pulmonary hypertension with fulminant HF can ensue and may even prove to be fatal. When the onset of MR is more insidious, the LA can dilate and hypertrophy, and a chronic compensated state without pulmonary hypertension may be sustained for many years. On the other hand, LA dilatation may be accompanied by atrial fibrillation with the potential for thrombosis and episodic embolization as a result of relative stasis of blood in the dyskinetic atrium.

Critical compensatory changes in LV hemodynamics are characteristic of chronic MR. Regurgitant volumes returning to the LV during diastole result in increased LVEDV and supranormal EFs, based both on standard Frank-Starling mechanics and the presence of LV ejection into the relatively low-resistance or low-afterload LA. Although net forward blood flow is reduced, this supranormal ejection serves to marginally unload the LV and normalize LVEDV. Wall stress resulting from increased LVEDV also leads to compensatory myocardial hypertrophy and restoration of normal wall tension, as per Laplace's law.

Although a hypertrophied and/or hyperdynamic LV is typical of acute or compensated chronic MR, the finding of diminished EF despite the afterload reduction associated with MR is suggestive of a decompensated state with rightward or downward shifts in Frank-Starling curve pressure-volume relationships (see Fig. 112.11). In this setting, net forward flows continue to decrease, and LVEDV increases. Consequent LA and LV dilatation lead to an increase in mitral orifice size. A self-perpetuating cycle of worsening HF with worsened MR eventually takes hold. LV failure may then lead to pulmonary hypertension and right-sided HF.

Diagnosis

Symptoms and signs. Acute decompensated MR may cause the sudden onset of dyspnea secondary to pulmonary venous hypertension and congestion. An associated decrease in forward cardiac output may cause hypotension or even hemodynamic collapse. More typically, patients with chronic, mild MR may be asymptomatic for most of their lives. When MR more gradually becomes moderate to severe, typical symptoms of left HF, atrial fibrillation, or even right HF may manifest.

Physical examination. Palpation of patients with MR may reveal a hyperdynamic, laterally displaced cardiac impulse. Auscultation typically reveals a holosystolic, high-pitched, blowing apical murmur that radiates to the axilla. Isolated posterior leaflet prolapse may cause the murmur to radiate to the sternum or aortic area, whereas isolated anterior leaflet prolapse may cause the murmur to radiate to the back or head. Other findings may include a diminished first heart sound, wide splitting of the second heart sound as a result of early aortic valve closure, or a third heart sound resulting from increased blood flow across the MV.

Diagnostic testing. Echocardiography is the mainstay of diagnosing and monitoring MR, although cardiac MRI can also provide useful regurgitant volume and cardiac function data. Routine chest radiography may demonstrate a widened cardiac silhouette, LA enlargement, or signs of pulmonary congestion associated with HF. ECG may reveal atrial fibrillation and/or signs of LA enlargement (p mitrale) and QRS or ST-T interval changes reflective of ventricular hypertrophy and/or bundle branch conduction abnormalities.

TTE and especially TEE studies allow precise visualization of the mechanisms responsible for inducing MR, including single or bileaflet prolapse and/or flail, enlarged or "billowing" leaflets, annular dilatation, chordal rupture, papillary muscle rupture, or restricted leaflet motion and tethering caused by an enlarged or infarcted ventricle. Leaflet disruption or perforation, valvular vegetations, or annular abscesses secondary to infective endocarditis may also be visualized.

Doppler analysis provides important prognostic data on regurgitant jet localization and quantification, typically based on flow dynamics related to the proximal isovolumetric surface area, which is seen on echo as a hemispheric area of flow convergence proximal to a regurgitant orifice (i.e., ventricular side of MR valves; Fig. 112.19). Analysis of the radius and the MR flow velocity in this flow convergence area allows calculation of the regurgitant fraction, ERO area, and regurgitant volume based on the following equation: flow = velocity × area. The flow convergence area narrows just downstream to the orifice of a regurgitant valve into a waist of the highest blood flow velocity as the regurgitant volume passes through the valve orifice, called the *vena contracta,* the width of which is also a marker of MR severity. Severe MR is thus now defined as an ERO $\geq 40\ \text{cm}^2$, a regurgitant volume ≥ 60 mL, RF $\geq 50\%$, a vena contracta ≥ 0.7 cm, a central MR jet $>40\%$ of the LA area, or a holosystolic eccentric jet.[10]

Natural History

Acute MR is typically caused by chordal rupture resulting from degenerative disease, papillary muscle rupture due to myocardial infarction, or infective endocarditis causing leaflet perforation or chordal rupture. It is typically poorly tolerated and often requires

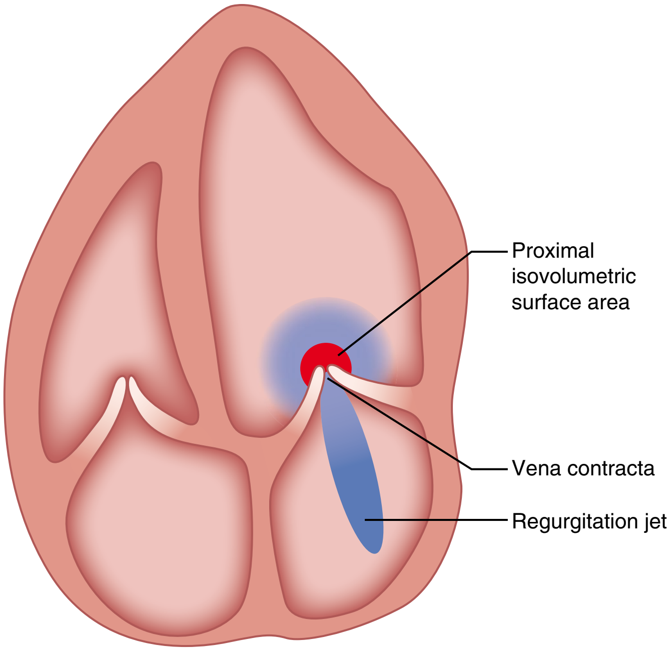

FIGURE 112.19 Echocardiographic assessment of severity of mitral regurgitation. The proximal isovolumetric surface area (PISA) is seen on echo as a hemispheric area of flow convergence proximal to a regurgitant orifice (i.e., ventricular side of mitral regurgitation [MR] valves). Analysis of the radius and the MR flow velocity in this flow convergence area allows calculation of the regurgitant fraction, effective regurgitant orifice (ERO) area, and regurgitant volume based on the following equation: flow = velocity × area. The flow convergence area narrows just downstream to the orifice of a regurgitant valve into a waist of highest blood flow velocity as the regurgitant volume passes through the valve orifice, called the *vena contracta,* the width of which is also a marker of MR severity.

urgent intervention. In the absence of intervention, severe pulmonary edema, cardiac decompensation, and/or the development of pulmonary hypertension often lead to rapid deterioration and poor outcomes.

The subacute/chronic asymptomatic MR patient was long thought not to pose an increased mortality risk, but a rich body of data developed over the past two decades now clearly demonstrates that even in the asymptomatic patient, the presence of severe MR with ventricular dysfunction, pulmonary hypertension, or atrial fibrillation carries a diminished prognosis.[10,57] Moderate primary MR has likewise now been shown to be associated with an annual mortality risk of 3% without intervention, representing excessive risk compared with results now achievable with mitral repair.[57]

Patients with functional ("secondary") MR, typically occurring on the basis of ischemic disease or dilated cardiomyopathy, carry a far worse prognosis than patients with primary MR.[57] Data from the Surgical Treatment for Ischemic Heart Failure (STICH) trial examining patients with ischemic heart disease and diminished LVEF (≤35%) demonstrated that mortality over approximately 4.5 years was about twofold greater in patients with moderate to severe MR compared with those with mild or no MR.[58]

Treatment

Medical management. The medical management of acute MR involves afterload reduction with vasodilators. The resultant decrease in aortic pressure and afterload enhances forward cardiac output and decreases regurgitant flow into the LA. When vasodilator use is ineffective or is limited by systemic hypotension, intraaortic balloon pump counterpulsation effectively lowers systolic afterload and increases forward flow. Prompt MV surgery is typically needed in acute MR, particularly in the symptomatic or hemodynamically compromised patient, but intraaortic balloon pump can be used to temporize surgery and stabilize the patient.

In symptomatic patients with chronic MR, standard vasodilator and diuretic medical therapy can be useful in improving ventricular hemodynamics and reducing pulmonary congestion. Diuretics may be particularly effective in reducing volume overload, ventricular distention, and symptoms but do not generally reverse pathologic changes. Contrary to popular practice, there is no evidence to support the use of vasodilators or other afterload-reducing medications in order to attempt to delay the need for surgery in asymptomatic patients with chronic MR and normal LV systolic function.[10]

For patients with functional, secondary MR, guideline-directed medical therapy (GDMT) and cardiac resynchronization may improve ventricular function (and sometimes degree of regurgitation) as well as provide symptom relief. Diuretics, angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor antagonists, β-blockers, and aldosterone antagonists are beneficial in the presence of HF. Recently, a landmark trial was the first to demonstrate the efficacy of a sodium-glucose cotransporter-2 (SGLT2) inhibitor, specifically dapagliflozin, in reducing cardiovascular death, HF hospitalizations, and urgent HF visits compared with placebo in patients with stable, chronic HF with LVEF <40%.[59] Currently, SGLT2 inhibitors are an established part of GDMT in HF patients with reduced EFs.

Surgical Treatment

Surgical indications for MR have broadened considerably as morbidity and mortality associated with surgery have decreased and the pathophysiology is better understood. Specifically, current understanding that the onset of ventricular dysfunction is associated with diminished prognosis and expectation for postoperative ventricular functional recovery has expanded indications to asymptomatic patients with severe MR regardless of LV function.

Surgery now carries a class I indication for asymptomatic patients with chronic severe primary MR and evidence of LV dysfunction (LVEF ≤60% or LV ESD ≥40 mm) as well as symptomatic patients irrespective of LV function (except for those who are high risk or prohibitive surgical risk with life expectancy >1 year, class IIa indication).[10] Further, because of these considerations, class IIa indications have now been added for asymptomatic patients with chronic primary severe MR and normal LV function (LVEF ≥60% and LVESD ≤40 mm), who have a 95% chance of successful mitral repair with <1% mortality with low surgical risk, and those with new-onset atrial fibrillation or resting pulmonary hypertension (pulmonary artery systolic pressure >50 mm Hg). Class IIb is reserved for those asymptomatic patients with normal LV function with progressive increase in LV size or decrease in EF on ≥3 serial imaging studies.[9] Patients with chronic moderate or severe primary MR undergoing cardiac surgery for other indications should undergo surgery.

It has been traditional to defer surgical treatment of functional MR, especially in the setting of coronary artery bypass surgery (CABG), under the presumption that improvements in the ischemic milieu after CABG would lead to the resolution of functional MR. Data from recent studies suggest, however, that deferring intervention for moderate to severe MR leads to worse outcomes in the setting of concomitant CABG.[58] As such, patients with chronic severe secondary MR undergoing aortic valve replacement or CABG should be considered for MV therapies.[10]

Repair of the MV is preferred over MV replacement for patients with primary MR when technically feasible and indicated. Successful MV repair provides an improved quality of life, with less morbidity and improved long-term event-free survival, when compared with MV replacement in appropriately selected patients. Mitral repair is considered very durable, with reoperation rates of less than 10% at 10 years when postoperative echocardiography demonstrates mild or absent MR.[60,61]

Repair can today be accomplished through a variety of techniques, including anterior or posterior leaflet resection with reconstruction, chordal transfer, leaflet folding plasty, edge-to-edge leaflet sutures, and creation of neochordae. Ring annuloplasty is indicated with all MV repairs because it has been clearly shown to improve the durability of repair. Some debate continues, however, about whether rings should be flexible or rigid, contoured or uniplanar, and completely or partially circumferential (open or closed).

The appropriate surgical intervention for patients with secondary MR is less clearly defined than for primary MR, with a growing understanding of the role of ventricular pathology in perpetuating ischemic MR undermining previous recommendations for using (exaggerated or undersized ring annuloplasty) mitral repair to correct this pathophysiology. Specifically, randomized controlled trial data from the Cardiothoracic Surgical Trials Network (CTSN) showed no difference in overall LV remodeling or survival for patients undergoing repair versus replacement but a higher 2-year rate recurrence rate for moderate or severe MR with repair versus replacement (59% vs. 4%, $P < 0.001$).[62] Likewise, although the addition of MV repair to patients undergoing CABG with moderate ischemic MR did significantly decrease the incidence of residual moderate or severe residual MR versus the CABG-alone group (11% vs. 32%, $P < 0.001$), MV repair failed to improve mortality.[63]

In the 2020 ACC/AHA guidelines, chordal-sparing MV replacement has a IIb indication over downsized annuloplasty repair for severely symptomatic patients with chronic secondary MR, and the usefulness of repair is downgraded to “uncertain” with a IIb recommendation for patients with moderate ischemic MR undergoing CABG.[10] Various new techniques, including papillary muscle “sling” procedures, are also consequently being tested to address primary subvalvular and ventricular pathology as the primary focus of secondary MR repair, but none has panned out to date.

A wide variety of surgical techniques may be employed to repair primary MR lesions. Most commonly, flail or prolapsing segments of the valve can be excised via limited triangular or more extensive quadrangular resections, and leaflet continuity is restored by suturing the resected leaflet edges back together (Fig. 112.20A). Relaxing incisions along the posterior leaflet base facilitate a sliding annuloplasty, which may be used to reduce tension on the repair and to decrease the height of the posterior leaflet. This helps prevent postresection MR resulting from systolic anterior motion (SAM) of the anterior mitral leaflet, which may become displaced toward the aortic outflow tract after inadequate resections.

Another option for mitral repair is the creation of neochordae, which can be created or preselected using Gore-Tex suture and should be sized to the height of the annulus. The neochordae are attached to the papillary muscle and the free edge of the leaflet to provide appropriate leaflet support and prevent leaflet prolapse.

A ring annuloplasty should be performed with all MV leaflet repairs because this maneuver has been shown to significantly

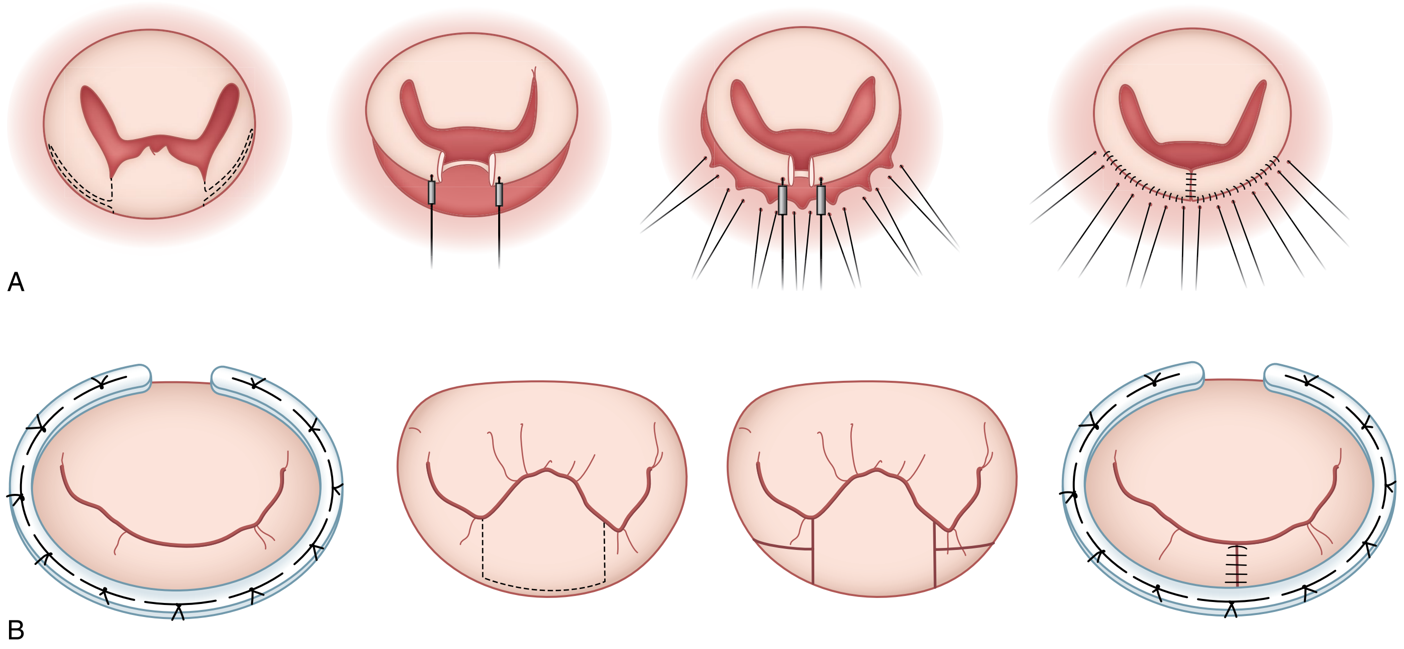

FIGURE 112.20 Mitral valve repair surgery. (A) Resection of leaflet tissue incorporating triangular or quadrangular resection, most commonly flail or prolapsing (typically posterior [P2]) segments of the valve. Leaflet continuity is restored simply by suturing the resected leaflet edges back together. (B) Annuloplasty ring. An annuloplasty ring is almost always implanted to supplement resectional repairs or may be used alone to address mitral regurgitation arising from a dilated annulus. Circumferentially placed simple, nonpledgeted sutures are typically used to implant annuloplasty rings in a manner similar to valve implantation.

improve the durability of repair and can be used as a stand-alone procedure to address MR arising from a dilated annulus (see Fig. 112.20B). Insertion of an annuloplasty ring helps restore normal annular geometry and ensure an appropriate coaptation zone of 6 to 8 mm between anterior and posterior leaflets. Numerous device options are available for annuloplasty, including rigid or flexible and partial or complete rings. Data are indefinite on which of these ring types provides the best outcomes.

Percutaneous therapies for MV disease are rapidly evolving. Various treatment options have been tested, including transcatheter mitral annuloplasty, which is both complex and technically challenging to place accurately, leading to mixed results. Chordal repair through transapical approaches has been tested but has not been widely used because these techniques are still quite invasive, with unknown durability. TEER models the surgical repair technique of Alfieri and colleagues to treat a prolapsed anterior leaflet by opposing the middle scallops of the anterior and posterior leaflets, leading to a double orifice. The MitraClip system, consisting of a steerable guide catheter and a clip delivery system, was the first developed and received FDA approval for high-risk patients in 2013 for degenerative MR.[64] The clip is introduced through the sheath into the left atrium via a transseptal puncture and is positioned under TEE guidance perpendicular to the line of coaptation at the pathologic segment (Fig. 112.21). Two randomized trials, Cardiovascular Outcomes Assessment of the MitraClip Percutaneous Therapy for Heart Failure Patients With Functional Mitral Regurgitation (COAPT) and Percutaneous Repair With the MitraClip Device for Severe Functional/Secondary Mitral Regurgitation (MITRA-FR), assessed the efficacy of treating patients with severe functional MR and systolic HF with the MitraClip device.[65,66] The use of the percutaneous device was found to be efficacious in patients with severe, functional MR treated rigorously with GDMT who also did not have as significant dysfunction. It has since received FDA approval to treat functional MR in 2019. Advancements in design with the clip system have continued to include devices with longer, wider clips and those designed with central spacers to decrease the regurgitant orifice area. With increasing experience with TEER, factors predicting failure have been identified, including patients with small MV orifice areas (<4.0 cm^2), large coaptation gap, insufficient leaflet length to grasp, significant clefts, severe MAC, or calcification of the involved leaflet. Transcatheter mitral valve replacement devices are currently under investigation. Although early studies have shown high rates of technical success to virtually eliminate MR, there remains an unacceptably high screen failure rate for enrollment in these trials because of the high risk of left ventricular outflow tract obstruction and large annular size exceeding currently available device sizes. Although stroke risk remains low, because most of the devices require anticoagulation, major bleeding complications have been reported. Treatment of failed MV repairs (mainly with complete ring annuloplasties) has been performed with TAVR valves in the mitral position, but long-term durability data are still pending.

Tricuspid Regurgitation and Other Right-Sided Valvular Disease

Nearly all the pathophysiologic mechanisms causing left-sided valve disease may analogously lead to primary right-sided valve disease. The most common presentation of right-sided valvular disease, however, is functional TR caused by RV failure or dilation (which itself is typically secondary to left-sided dysfunction and pulmonary hypertension). Functional etiology secondary to left-sided valve disease is responsible for TR in 80% to 90% of cases. Less commonly, functional TR may also be caused by RV infarction or ischemia. Transvalvular pacemaker or cardioverter-defibrillator leads can also uncommonly cause mild or even higher-grade TR.

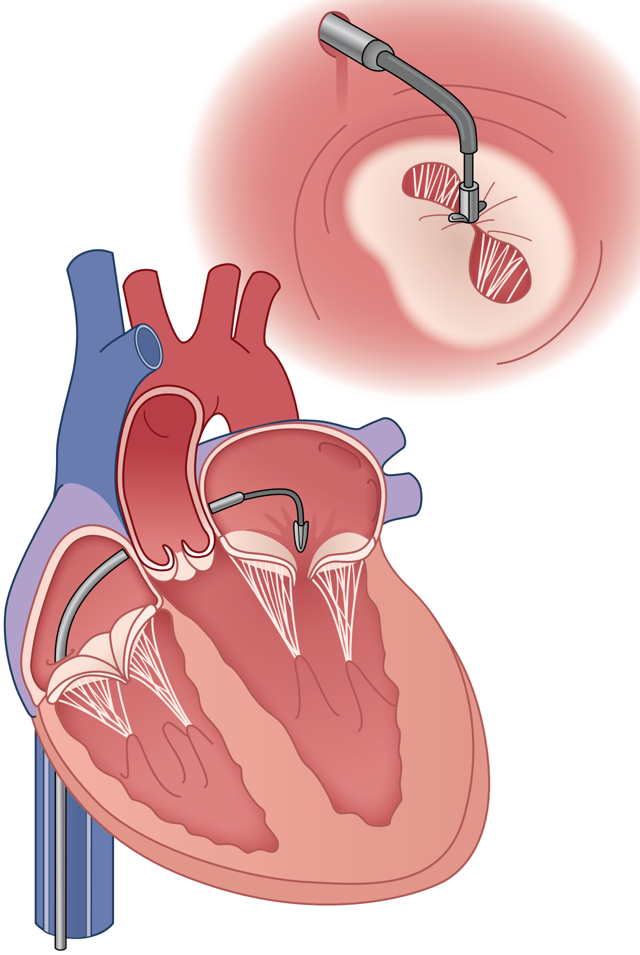

FIGURE 112.21 Percutaneous mitral valve repair. Using a catheter-based clip delivery system, the operator grasps the mitral valve leaflet edges and places a clip that emulates the edge-to-edge leaflet repair. Tricuspid stenosis (TS) occurs infrequently in developed countries because rheumatic disease accounts for over 90% of such lesions. Carcinoid syndrome is the most common of a group of unusual disorders that lead to the deposition of pathologic materials in the tricuspid and/or pulmonic leaflets as a far less frequent cause of primary TR, TS, or pulmonic valve disease.

Congenital anomalies causing pulmonic valve stenosis, often associated with tetralogy of Fallot, tricuspid atresia, and TR occurring as part of the Ebstein anomaly, are three of the most common of the congenital disorders leading to right-sided valve disease.

Pathophysiology

TR accounts for most right-sided valvular disease, of which secondary or functional TR is the most prevalent. Secondary TR is most often the result of left-sided valve disease and/or HF.

Primary causes of TR include endocarditis; rheumatic valvular disease; carcinoid disease; and iatrogenic injuries, including injuries resulting from pacemaker/defibrillator implantation. Unlike left-sided disease, altered RV mechanics and geometry associated with RV failure may cause irreversible dilatation of the saddle-shaped ellipsoid of a healthy tricuspid annulus into a more planar circular shape, leading to persistence of TR despite the correction of inciting hemodynamics. Increased central venous pressure resulting from tricuspid valve disease can lead to venous congestion, hepatic enlargement, ascites, and peripheral edema as well as right atrial enlargement and arrhythmias. Decreased RV output can lead to LV underfilling and inadequate left-sided output.

Diagnosis

Symptoms and signs. Because patients with tricuspid disease almost invariably have coexisting left-sided valve disease, it is difficult to separate symptoms of tricuspid pathology from those of multivalvular disease, and tricuspid valve disease itself may frequently be asymptomatic. Dyspnea, fatigue, and exercise intolerance may result as HF develops.

Physical examination. A holosystolic murmur that increases with inspiration (Carvallo sign) and that may be heard along the sternal border is typical of TR. With TS, an opening snap followed by a diastolic rumble may be heard at the right sternal border. The physical examination of patients with tricuspid valve disease may otherwise reveal only jugular venous distention with a prominent systolic “v” wave. With progressive central venous congestion, physical findings are often out of proportion to symptoms and may include pleural effusions, hepatic enlargement (pulsatile liver typical of TR), abdominal tenderness, ascites, and peripheral edema.

Diagnostic testing. Because of the overlay of concomitant left-sided disease, echocardiography is the sole reliable testing modality useful in assessing tricuspid disease. Severe TR is defined by a central jet ≥50% right atrium, vena contracta width ≥0.7cm, ERO ≥0.4 cm^2, regurgitant volume ≥45 mL, and hepatic vein systolic flow reversal. Estimation of PASP based on the velocity of the TR jet measured by continuous-wave Doppler is a useful prognostic criterion. An annular diameter of greater than 40 mm defines significant tricuspid annular dilation and is also an important consideration when selecting appropriate treatment for TR.[67]

Natural History

Decreased survival is associated with increasing TR severity, regardless of other indices of cardiac function. Although patients who undergo surgical treatment of left-sided valve disease may experience improved or resolved functional TR, such improvement is highly unpredictable, and survival for patients with uncorrected moderate to severe TR has been reported to be less than 50% at 4 years.[68]

Treatment

Medical management. The medical treatment of tricuspid valve disease involves optimization of RV preload and afterload, using diuretics and ACE inhibitors, respectively. If atrial fibrillation is present, rate control may optimize diastolic filling. With functional TR, medical treatment to reduce pulmonary hypertension may also improve cardiac output.

Surgical Treatment

The timing and method of surgical treatment for functional TR are controversial. Classic teaching from the early years of MV replacement was that functional TR would improve after primary left-sided valve treatment. This led to the recommendation of avoiding tricuspid surgery in most cases. This has proven not to be a reliable strategy. Left uncorrected, secondary TR will worsen in about 25% of patients, which has functional and survival implications resulting from irreversible progression of RV damage and organ failure.[68] Further, although adding tricuspid repair during left-sided heart surgery does not significantly increase operative risk, reoperation due to persistent TR after left-sided heart surgery carries a perioperative mortality of 10% to 25% or greater.

On the basis of these considerations, severe TR has emerged as a class I indication for concomitant tricuspid valve surgery in patients who are undergoing left-heart surgery.[10] Concomitant repair is also probably indicated in those with mild or greater TR and either tricuspid annular dilation (>40 mm diameter) or evidence of right HF (class IIa).[10,69] Additionally, patients with symptomatic severe primary TR unresponsive to medical therapy are candidates for tricuspid valve surgery (class IIa), as are patients with moderate TR and pulmonary hypertension (class IIb) and asymptomatic or minimally symptomatic patients with evidence of progressive RV dysfunction (class IIb).

Tricuspid valve repair is generally preferred to replacement whenever possible. For severe TR due to isolated annular dilation, annuloplasty using a prosthetic ring has been shown in several studies to have better long-term results than any suture annuloplasty technique.[11,12] Valve replacement should be considered for functional TR resulting from severe leaflet tethering and RV remodeling or leaflet fibrosis and retraction, such as occurs with carcinoid heart disease (which also less commonly involves the pulmonary valve).

Symptomatic patients with isolated TS do not benefit from medical management and are best treated with valve replacement. In adults, TS is almost nonexistent, except for the most advanced cases of RHD, endocarditis resulting from a vegetation, or functional TS resulting from a large intraatrial mass obstructing outflow. Most TS generally is the consequence of a congenital anomaly. Those with TS and left-sided valve disease should likewise undergo concomitant correction during the same operation. Percutaneous tricuspid valvulotomy may be considered, but outcomes are less optimistic than those seen with MS and may induce significant TR.

Experience with percutaneous treatment of severe TR started with compassionate and off-label use of the MitraClip system as part of the Transcatheter Tricuspid Valve (TriValve) Registry. The majority of patients (77%) had successful treatment of their TR to grade 2 or less, and this was associated with improved survival and decreased HF hospitalizations. Of note, over half the patients in that cohort also had their MR treated in the same procedure.[70] The Trial to Evaluate Cardiovascular Outcomes in Patients Treated With the Tricuspid Valve Repair System Pivotal (TRILUMINATE Pivotal) demonstrated that TriClip was safe in the treatment of severe, symptomatic TR to reduce the severity of TR and to improve quality-of-life metrics at 1 year.[71] In April 2024, this device received approval from the FDA to treat patients with severe TR at intermediate or high risk for open-heart surgery. The first transcatheter tricuspid valve replacement device, the EVOQUE system, received FDA approval in February 2024 after the Transfemoral Tricuspid Valve Replacement: Investigation of Safety and Clinical Efficacy (TRISCEND) study reported its 1-year outcomes in treatment of patients with greater than or equal to moderate, symptomatic TR. The trial demonstrated

TR reduction, improved survival, and low hospitalization rates.[72] Similar to the mitral space, transcatheter tricuspid valve technologies are rapidly emerging, yet durability data and long-term outcomes of treatment of advanced TR are still lacking.

Mixed Valve Disease

Patients with mixed valve disease typically present with a predominant lesion that dictates symptoms and pathophysiology. There are very limited data on the natural history of mixed valve disease; therefore, the optimal timing of serial evaluation is not clear. Patients with multivalvular disease likewise present even more complex diagnostic and therapeutic challenges than patients with single-valve disease. The coexistence of aortic valve disease and MR, for example, will mitigate LV changes induced by aortic valve pathology but worsen pulmonary and right-sided complications.

Limited data are available to guide treatment in cases of multivalvular disease, and indications for interventions should be based on symptoms and objective analysis of surgical outcome rather than severity indices for the individual lesion. In general, therapy should be targeted to the predominant lesion while considering the severity of concomitant valve disease.

  Mitral Valve Anomalies
Summary

This chapter is designed to provide medical students, general surgery residents, and practicing general surgeons with a working tool to aid in their understanding of the features of anatomy and physiology in patients presenting for general surgical procedures in the setting of repaired or unrepaired congenital cardiac lesions. The large scope and breadth of the evolving field of congenital heart surgery precludes an exhaustive treatise on all aspects of this specialty. Several excellent and thorough textbooks on congenital heart surgery are referenced in this chapter, and the reader is encouraged to use them for additional in-depth understanding of the lesions to be reviewed. A general surgeon practicing today needs to be well versed in the basics of cardiac anatomy, physiology, and specific derangements associated with the various known congenital cardiac lesions. Furthermore, few patients with complex congenital cardiac lesions may be considered cured of their cardiac problem, even after successful reconstructive surgery. Thus, it is imperative that a general surgeon who needs to perform a noncardiac operation on such a patient be familiar with the specific issues of ongoing concern in patients with congenital cardiac disease.

HISTORY AND OTHER CONSIDERATIONS

The era of surgical treatment for congenital cardiac anomalies was initiated in November 1944, when Alfred Blalock and associates Vivien Thomas and Helen Taussig combined their unique talents and vision to treat a young child dying of cyanotic congenital heart disease (CHD).[1] This palliative operation involved the surgical creation of a systemic pulmonary artery connection in the patient, who had inadequate pulmonary blood flow. The procedure has since been recalled as miraculous and now, more than 75 years later, is known by the eponym *Blalock-Taussig-Thomas* (BTT) shunt. The striking success of this simple concept and the reproducible nature of the operation in children with otherwise fatal cardiac conditions have emboldened subsequent surgical innovators to venture inside the congenitally malformed heart. At first, the parent was asked to serve as a biologic oxygenator using the technique of controlled cross-circulation; soon thereafter, the mechanical, extracorporeal, heart-lung bypass pump was developed.[2,3] With the aid of this ability to support the patient's circulation during intracardiac exploration, surgeons have sequentially attacked almost every described congenital cardiac anomaly. The prospect of meaningful survival for patients born with otherwise devastating congenital cardiac lesions is now expected in most cases.

As a result of this success story, there is now a large and growing population of adults with repaired or unrepaired CHD; estimates in the United States for 2010 placed the number of adult patients surviving with repaired or palliated congenital cardiac lesions at more than 1.4 million.[4] There has been an increase of greater than 50% in CHD prevalence since 2000, and by 2010, adults accounted for two-thirds of patients with CHD in the general population.[5] This reality has been associated with new challenges in the ongoing medical maintenance of such patients, with particular focus on the care of patients with congenital cardiac lesions presenting for surgery for noncardiac illnesses. The evolving subspecialty of adult CHD and accredited adult CHD centers points to the unique needs of this population of patients.

PATHWAYS FOR PRACTICING CONGENITAL HEART SURGERY

Before embarking on a review of the field, it is worthwhile to describe the setting in which patients with CHD seek and receive care in today's medical environment. With the development of sophisticated methods of fetal ultrasound, a large percentage of children requiring surgery for CHD are diagnosed during gestation (Fig. 113.1). A fetal diagnosis of complex CHD is extremely helpful to parents and the medical management team. Fetal diagnosis is particularly important in the setting of lesions dependent on persistent patency of the ductus arteriosus for postnatal survival. In these individuals, survival after delivery is predicated on the maintenance of ductal patency through the intravenous infusion of prostaglandin E1 (PGE1) initiated in the delivery suite, often through an umbilical vein catheter. Several studies have shown a decrease in morbidity, but there is inconclusive evidence that mortality rates are decreased.[6,7]

A growing number of congenital cardiac lesions are known to be associated with specific genetic mutations, many clearly inherited and some presumed to be sporadic. A chromosomal analysis is frequently performed in individuals found to have major structural cardiac abnormalities; this analysis may be performed during gestation through amniocentesis or after delivery. The chromosomal evaluation is beneficial to the family when planning the risk of such an occurrence in future offspring. For the clinician, knowledge of chromosomal abnormalities, such as DiGeorge sequence, velocardiofacial syndrome, and Marfan syndrome, aids in the delivery of acute medical management.

In general terms, the timing of surgery for various congenital cardiac conditions depends on the presenting symptoms and expectations for further associated complications. Neonates presenting with limited pulmonary blood flow or atretic pulmonary connections typically require surgery during the first few days of life and occasionally within hours of delivery. Lesions associated with excessive pulmonary blood flow result in early heart failure, which may manifest as poor feeding, tachypnea, or respiratory failure. These patients are operated on during early infancy to ameliorate their symptoms and prevent the development of irreversible pulmonary vascular disease.

Preterm and low-birth-weight infants with CHD have been presenting for surgical consideration with more frequency. This treatment strategy requires thoughtful planning and coordination among the surgery, anesthesia, cardiology, intensive care, and neonatology teams. We have successfully operated on two 800-g infants with transposition of the great arteries (TGA).

The specialty of congenital heart surgery is now recognized as a subspecialty of cardiothoracic surgery. Congenital heart surgeons were previously certified in cardiothoracic surgery by the American Board of Thoracic Surgery and received additional fellowship training in the United States or abroad in congenital heart surgery. As of 2009, the American Board of Thoracic Surgery offers a formal certification process for subspecialty training in congenital heart surgery. At the present time, there are 17 congenital cardiac surgery residency programs approved by the Accreditation Council for Graduate Medical Education.[8] Most pediatric cardiac surgery is performed in large, multispecialty children's hospitals in association with formal programs focused on the care of these complex patients. The management team includes pediatric cardiac anesthesiologists, perfusionists, and nursing staff. Focused pediatric cardiac intensive care units have been developed to optimize the patients' opportunity for recovery.

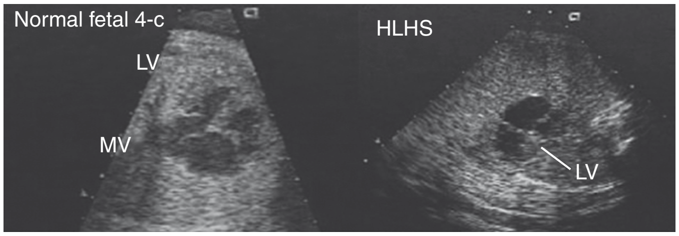

FIGURE 113.1 Normal fetal ultrasound (four chamber *[4-c]; left*) and fetal ultrasound of a child with hypoplastic left heart syndrome *(HLHS) (right). LV,* Left ventricle; *MV,* mitral valve.

Historically, pediatric cardiologists have provided the medical management of patients born with CHD. Pediatric cardiology is also evolving. With advances in catheter-based technology, interventional pediatric cardiologists are now addressing lesions previously treated with surgery. Examples include device closure of atrial septal defects (ASDs) and ventricular septal defects (VSDs), occlusion of patent ductus arteriosus (PDA), and dilation and stenting of stenotic vessels in the systemic and pulmonary circulation. For a more in-depth review of this specialty, see the excellent technical text by Mullins.[9]

The care for adults with CHD is in evolution. This issue is of particular relevance to the general surgeon faced with operating on an adult patient with significant CHD. One overriding message needs to be clear to the general surgeon in this setting: It must be assumed that in patients with previously repaired congenital cardiac lesions, even without overt cardiac symptoms, the potential for significant perioperative cardiorespiratory derangement exists. More simply stated, the presence of a surgical scar on the chest of a patient with known CHD does not suggest that the lesion has been cured. With this message firmly in mind, the general surgeon may find it challenging to determine the best source for a qualified consultation for such a patient. At the present time, many adult cardiologists are not adequately trained in CHD to provide competent consultation on adult patients with CHD.

Pediatric cardiologists are not educated in adult medicine and cardiology, and many feel uncomfortable providing consultation on adult patients with CHD. The subspecialty of adult CHD is currently becoming more formalized, but the number of physicians who have been educated specifically to care for these patients is still few. In 2015, the American Board of Internal Medicine offered the first certification examination in Adult Congenital Heart Disease. The Accreditation Council for Graduate Medical Education–accredited fellowship became available in 2019, with 28 accredited programs currently.[10,11] The practicing general surgeon needs to become familiar with the specific issues of concern for patients with CHD to ascertain that the patient's unique anatomic and physiologic issues have been evaluated properly. A pediatric cardiologist, in coordination with an adult cardiologist, must evaluate adult patients with CHD who present for care in a center without a designated qualified specialist. Of equal importance, the anesthesiologists and intensivists caring for an adult patient with CHD must have a working understanding of the complexities and nuances of the patient's cardiac condition. The anesthetic management of patients with CHD undergoing general surgical procedures is complicated and can become disastrous if managed improperly.

ANATOMY, TERMINOLOGY, AND DIAGNOSIS

Anatomy and Terminology

One of the most intimidating aspects for the student of CHD is developing a level of comfort with the terminology used for describing specific lesions. A thorough and sound understanding of normal cardiac anatomy is mandatory. There are several excellent texts on this subject; in particular, the text edited by Wilcox and coworkers[12] is especially concise and clear. One difficulty that challenges proper understanding of anatomy is the frequent use of abbreviations and eponyms for various congenital lesions—for example, *congenitally corrected TGA* (ccTGA), *ventricular inversion,* and *L-transposition* all describe the same heart, but none provides a complete anatomic description. Unless otherwise clear to all clinicians involved in the care of these complicated patients, the anatomic description needs to be segmental and complete to avoid mistakes and misinterpretations of structure.

In describing congenital cardiac lesions, a segmental approach is used to determine the relationship of the various structural elements. The situs describes the relationship of sidedness—situs solitus (normal), situs inversus (reversed), or situs ambiguus (indeterminate). The cardiac elements described include (in sequence) the atria, ventricles, and great vessels. The relationship of the connections must be understood; connections are concordant (e.g., the right atrium connecting to the right ventricle [RV]) or discordant (e.g., the RV connecting to the aorta). The chamber sidedness must be clarified (e.g., a morphologic right atrium may be on the left side of the patient). The relationship and connections of the cardiac valves must then be assessed; connections may be normal, stenotic, atretic, or straddling. Of note to the general surgeon, abnormal sidedness of the cardiac structures is frequently associated with abnormal relationships of the thoracic and abdominal organs. A thorough assessment of the patient's anatomy is recommended before surgery. Commonly used tools in evaluation of anatomy include echocardiogram, computed tomography (CT), magnetic resonance imaging (MRI), and cardiac catheterization.

There are two widely accepted and applied schools of cardiac morphologic description. The Van Praagh nomenclature uses abbreviations to describe the relationship of the atria, ventricular looping, and position of the aorta sequentially. The first letter describes the situs of the atrial chambers (and usually the abdominal organs): "S" for situs solitus (normal), "I" for situs inversus (reversed), or "A" for situs ambiguus (indeterminate). The second letter describes the relationship of the embryologic looping of the ventricles: "D" for dextro looping or right-handed topology (normal) or "L" (levo) for left-handed topology. The third and last letter describes the relationship of the aortic valve to the pulmonary valve: "D" for right-sided and "L" for left-sided as well as "S" for solitus and "I" for inversus (Fig. 113.2).

The Anderson nomenclature is more wordy and longer but is perhaps simpler to understand. The descriptions are again of the sequential relationship of the structures. Starting with the atria, the connections and relationships are sequentially described. Thus, the atrial sidedness is described, followed by the sequence of connections to the ventricles and then great vessels. For example, "atrial situs solitus (normal) with atrioventricular (A-V) discordance (reversed) and ventriculoarterial (V-A) discordance (reversed)" describes the heart mentioned earlier as corrected transposition, or S,L,L by the Van Praagh classification (Fig. 113.3).

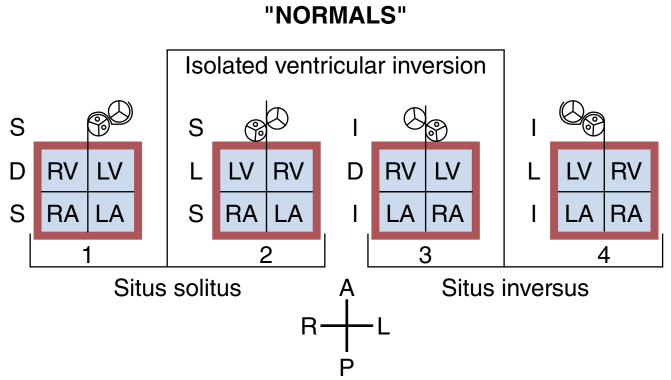

FIGURE 113.2 Model depicting cardiac morphology for normal hearts—that is, hearts with atrioventricular concordance and ventriculoarterial concordance—using Van Praagh nomenclature. The *vertical line* above the box denotes the position of the ventricular septum. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. (From Kirklin JW, Barratt-Boyes BG. General considerations: anatomy, dimensions, and terminology. In: *Cardiac Surgery*. 2nd ed. New York: Churchill Livingstone; 1993.)

Atrial situs solitus (normal) with atrioventricular discordance and ventriculoarterial discordance using Anderson nomenclature, S,L,L by Van Praagh classification. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *MV,* mitral valve; *PA,* pulmonary artery; *RA,* right atrium; *RV,* right ventricle; *TV,* tricuspid valve.

Diagnosis

As with all aspects of surgery, widely varying, highly sophisticated diagnostic tools are available to examine cardiac structure and function. Despite the widespread availability and application of these tools, none has replaced or eliminated the necessity of a thorough history and physical examination. Most patients who have a history of CHD become very well informed about the specifics of their cardiac conditions, as do their parents. A detailed review of the patient's past medical history is mandatory. This review includes, when possible, securing records from all previous diagnostic and procedural reports. An incorrect assumption is often made about a patient's previous surgical history and anatomy, frequently in a setting in which a patient's old operative report or clinical summary could easily clarify the misunderstanding.

In adults with CHD, in particular, there are specific points of medical history that must be elucidated. A history of palpitations, syncope, and neurologic deficit must be investigated further. The incidence of significant dysrhythmias in certain categories of adults with CHD is high and, in many cases, warrants further investigation, including continuous monitoring (Holter or Bardy), electrophysiologic study, or provocative testing.

Physical Examination

A complete physical examination in a patient with previously repaired CHD often yields critical information for the proper planning of a general surgical procedure. Patients need to be completely undressed and thoroughly examined. In many cyanotic patients, color changes may be prominent, particularly in the nail beds, lips, and mucous membranes. Clubbing of fingers may be noted. In other patients, cyanosis may be more subtle, giving the patient a gray or even pale appearance. Previous surgical incisions need to be noted and reconciled with the known medical history. Thoracotomy incisions on either side may indicate a previous BTT shunt using the turned-down, divided subclavian artery or with a prosthetic interposition graft—the so-called modified BTT shunt. In patients with a left aortic arch, a left thoracotomy incision is present if a previous coarctation repair has been carried out. Median sternotomy incisions or anterior thoracotomy incisions may indicate previous intracardiac or extracardiac surgery.

A complete vascular examination is often overlooked in patients with CHD. It is important to assess pulses and obtain blood pressure measurements in all four extremities. Patients who have an existing or have previously had a BTT shunt often have diminished or absent pulses in the upper extremity corresponding to the previous shunt. Also, patients with previous coarctation repairs may have diminished or absent pulses in the left upper extremity, especially if a subclavian flap angioplasty was performed (Waldhausen procedure). Furthermore, a history of previous coarctation repair does not guarantee that the lower extremity pulses and blood pressures will be normal. Moreover, patients who have undergone previous cardiac catheterization may have chronically stenosed or occluded femoral vessels. All these issues may be of significance for monitoring and vascular access in a patient undergoing a general surgical procedure.

Later in this chapter, the Fontan procedure for single-ventricle palliation is reviewed. Briefly, this operation results in significant systemic venous hypertension, often measuring 12 to 15 mm Hg (normal 0–8 mm Hg). In patients with a Fontan circulation, physical examination may reveal hepatic congestion, ascites, pedal edema, venous varicosities, and jugular venous distention. In some patients, macronodular hepatic cirrhosis may be suspected on the basis of a firm, fibrotic liver edge on palpation.

Entire textbooks have been dedicated to the physical examination of patients with cardiac disease, and a thorough discussion of this issue, particularly the specifics of cardiac auscultation, is beyond the scope of this chapter. In general, the cardiac examination includes an assessment of the patient's rhythm, point of maximal impulse, and character of any auscultated murmurs. Importantly, the absence of a significant cardiac murmur does not rule out significant cardiac pathology.

Diagnostic Tests

Pulse oximetry. Four-extremity pulse oximetry is an essential part of the clinical assessment of a patient with suspected CHD. Patients with ductal-dependent circulation to the lower body (severe aortic coarctation or aortic arch interruption) may present with differential cyanosis. This presentation indicates the ejection of desaturated pulmonary arterial blood through the patent ductus to the descending aorta contrasted with fully saturated pulmonary venous blood ejected to the ascending aorta and the upper extremities. Baseline (room air) saturation must be documented in all patients for whom an operative intervention is anticipated to establish their normal range and to allow for identification of changes throughout the perioperative period.

Plain radiography. Standard chest radiography with anteroposterior and lateral views is still an essential component of the assessment of a patient with CHD. Standard elements to be examined include a skeletal survey, assessment of the diaphragms, hepatic shadow, and location of the gastric bubble. The lung fields are assessed for pulmonary plethora (arterial or venous), air space disease, and the presence of effusions. The cardiac silhouette may reveal essential information, such as a cardiothoracic ratio indicative of cardiomegaly or pericardial effusion, the presence of atrial enlargement, the presence or absence of the pulmonary artery shadow, and arch sidedness (Fig. 113.4).

Electrocardiography. The electrocardiogram (ECG) is important in assessing patients with CHD. The rate and rhythm must be noted, including the presence or absence of P-wave activity and axis. Many patients with CHD, especially patients with complex conditions, such as heterotaxy syndrome, may exhibit deranged or absent sinus node activity, giving rise to a predominant junctional rhythm, which may significantly compromise cardiac output. The QRS duration and axis reveal information concerning conduction delay and abnormal ventricular forces. For example, patients with A-V canal defects are known to have left axis deviation. Furthermore, in patients undergoing repair of certain forms of CHD, there may be an early or late predisposition to malignant dysrhythmias. It is particularly important to elucidate a history of palpitations from a patient with repaired or unrepaired CHD; such a history may warrant further investigation with 24-hour continuous ECG monitoring (Holter) or longer-term monitor (Bardy).

Echocardiography. Noninvasive imaging is well established as the primary diagnostic modality for structural cardiac disease. For most patients, excellent anatomic detail may be obtained using two-dimensional transthoracic imaging. Standard images include subcostal, suprasternal, parasternal, and subxiphoid views and are oriented in long- and short-axis directions. Furthermore,

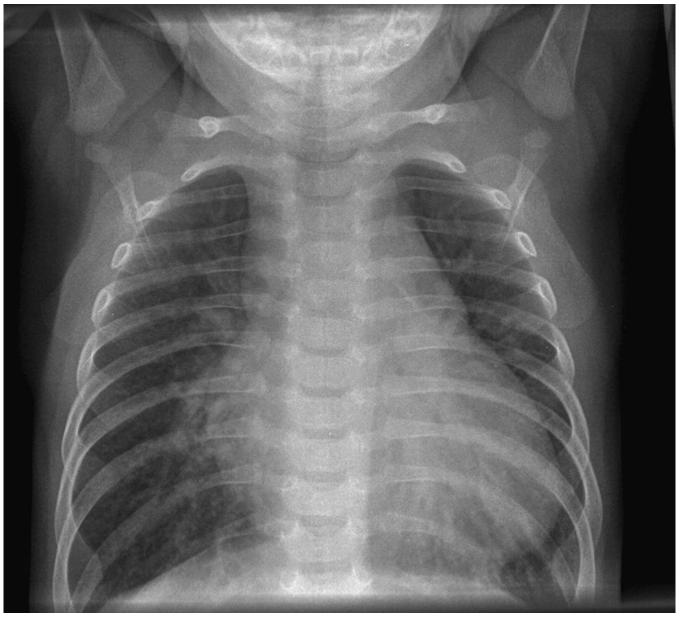

FIGURE 113.4 Cardiomegaly and increased pulmonary vascular markings in a patient with complete atrioventricular canal defect.

significant hemodynamic information may be inferred using echo Doppler blood flow velocities and interpreted using the modified Bernoulli formula (pressure gradient = $4V^2$, where V is echocardiographic velocity in meters per second). To assess the patient's cardiac lesion properly, segmental analysis of the cardiac structures, connections, and valves must be performed. A quantitative estimate of ejection fraction, shortening fraction, and valvular inflow velocity aids in assessing cardiac function. For most patients with CHD, adequate diagnostic information is attainable through echocardiography in the hands of a qualified pediatric cardiologist.

Magnetic resonance imaging and computed tomography. Cardiac MRI and CT are adjuncts to echocardiography for noninvasive structural and functional assessment of the heart. MRI has been used with increasing frequency to provide anatomic and functional detail in congenitally malformed hearts in which echocardiographic detail is lacking or unattainable. Cardiac MRI has proved particularly useful for imaging the extracardiac great vessels and systemic and pulmonary venous connections and for providing accurate estimates of cardiac function, especially right ventricular ejection fraction. MRI has the added benefit of using nonionizing electromagnetic fields. CT may also be used for such imaging detail but has the potential detrimental association with significant radiation exposure. A CT scan of the chest averages 5 to 7 mSv, and CT coronary angiography averages 9 to 11 mSv (chest x-ray: 0.1 mSv).[13]

Cardiac catheterization. Cardiac catheterization was long considered the gold standard for diagnostic imaging of congenitally malformed hearts. With the current sophistication of echocardiography, CT, and MRI, this is no longer the case for most patients. Nonetheless, there are still circumstances in which diagnostic cardiac catheterization is necessary to obtain accurate anatomic detail. One such circumstance may be patients who have poor echocardiographic windows, although even this issue may be overcome using transesophageal echocardiography. More often, there are specifics of anatomic detail that neither echocardiography nor MRI can delineate, such as branch pulmonary artery (or segmental) stenosis, origin and course of aortopulmonary collateral vessels, fistulous connections, and intracardiac communications (septal defects) not clarified by other imaging modalities.

Usually, diagnostic cardiac catheterization is performed to obtain precise hemodynamic information needed to make an informed assessment of the consequences of the patient's cardiac lesions. Using oximetric measurements, pressure data, and thermodilution cardiac output determination, accurate assessment of the patient's hemodynamic profile is obtained. Measured or derived data include central venous pressure; atrial pressure; ventricular pressures (including end-diastolic pressure); shunt fraction (in the case of ASDs or VSDs); pulmonary artery pressures; pulmonary capillary wedge pressure; systemic arterial pressure; and segmental oximetry of cardiac structures, including systemic and pulmonary venous return (Fig. 113.5). Thus, critical information is obtained about the presence and degree of shunting, systemic and pulmonary vascular resistance (PVR), and cardiopulmonary function. In certain clinical settings, these data are mandatory for a successful clinical management strategy. This may be particularly true for an adult patient with CHD requiring noncardiac surgery.

A thorough understanding of normal cardiorespiratory physiology is critical in interpreting data obtained by cardiac catheterization in a patient with CHD. Specifically, the normal pressure range, pulse waveforms, and oxygen saturations for the various cardiac chambers must be compared against data obtained in a deranged circulation. In the atria, there are characteristic waveforms—the *a* wave corresponding to atrial contraction, the *c* wave corresponding to A-V valve closure, and the *v* wave corresponding to atrial filling from venous return against the closed A-V valve.

FIGURE 113.5 Hemodynamic information obtained after cardiac catheterization.

Typical normal right atrial mean pressures range from 1 to 5 mm Hg, and left atrial mean pressures range from 2 to 10 mm Hg. Right ventricular pressure tracings in normal hearts demonstrate a more gradual upstroke when compared with the left ventricle. Filling or end-diastolic pressures in both ventricles are between 2 and 10 mm Hg in normal hearts. The normal right ventricular systolic pressure (and thus pulmonary artery systolic pressure) is 15 to 30 mm Hg, and the left ventricular systolic pressure is 90 to 110 mm Hg.

In normal hearts, there is a small, physiologically insignificant right-to-left shunt, which results from ventilation-perfusion (V/Q) mismatch in the lungs and coronary venous return directly to the left ventricle (thebesian venous return). This physiologic shunt represents less than 5% of the cardiac output and, in normal circumstances, does not produce detectable systemic arterial desaturation. Thus, significant systemic arterial desaturation represents a pathologic finding, consistent with pulmonary disease, intracardiac shunting, or both. As noted, the origin and degree of intracardiac shunting may be assessed by echocardiography. However, in certain circumstances, cardiac catheterization is necessary to measure cardiac oximetry, calculate shunt fraction, and derive systemic and PVR. Using a derivation of the Fick principle, the ratio of pulmonary blood flow (Qp) to systemic blood flow (Qs) can be determined as follows:

$$\mathrm{Qp/Qs} = (Sa_{O2} - \bar{\mathrm{M}}\mathrm{O_2\ sat})/(\bar{\mathrm{P}}\mathrm{O_2\ sat} - Pa_{O2})$$

where SaO_2 is systemic arterial oxygen saturation, $\bar{M}O_2$ sat is mixed venous oxygen saturation, $\bar{P}O_2$ sat is pulmonary venous oxygen saturation, and PaO_2 is pulmonary arterial oxygen saturation. Thus, in a patient with $\bar{M}O_2$ sat of 60%, $\bar{P}O_2$ sat of 100%, Sao_2 of 100%, and Pao_2 of 80%, the equation is as follows:

$$\mathrm{Qp/Qs} = (100-60)/(100-80) = 40/20 = 2:1$$

Calculating pulmonary vascular resistances may also be crucial in determining operability in a patient with CHD. In many settings, a precise measure of vascular resistance is unnecessary based on the clinical evidence. For example, in a small child with a large VSD seen on echocardiogram, the clinical findings of tachypnea, cardiomegaly, and failure to thrive confirm a large left-to-right shunt and infer acceptable PVR. However, in less clear circumstances, a precise calculation may be important in clinical decision-making. The PVR may be calculated from cardiac catheterization data as follows:

$$\mathrm{PVR} = \frac{(\text{Mean PA pressure [mm Hg]} - \text{Mean LA pressure [mm Hg]})}{\textit{Pulmonary Blood Flow (Qp) [L/min/m}^2\textit{]}}$$

In general, patients with an elevated PVR are further evaluated with pulmonary vasodilation—hyperventilation, hyperoxygenation, and inhaled nitric oxide—to determine whether the PVR is responsive. This information may be critical for patients who are otherwise marginal surgical candidates.

Finally, cardiac catheterization has been evolving as the primary therapeutic method for many important structural cardiac defects. In many children's hospitals, most catheterizations now performed are for interventional procedures rather than diagnostic procedures. This fact may be particularly pertinent to a general surgeon faced with treating a patient with a previous catheter-based correction of a cardiac defect. For example, the patient may have had an ASD or VSD closed with an occluder device in the past. This information may have important ramifications for infectious exposure and vascular access.

PERIOPERATIVE CARE

Perioperative management of a patient with unrepaired or palliated CHD can be extremely challenging. Standard hemodynamic, respiratory, and pharmacologic manipulations appropriate for structurally normal hearts may be entirely inappropriate in settings of complex CHD. This is especially true in the operating room and intensive care settings. General rules include a thorough knowledge of the patient's intracardiac anatomy and expected physiology. It is possible to make significant management errors based on incorrect physiologic expectations in the setting of incomplete understanding of the patient's anatomy. For example, in a patient with unrepaired tetralogy of Fallot (TOF) and associated significant right ventricular outflow tract obstruction (RVOTO), it is expected that the patient will exhibit some degree of systemic arterial desaturation. However, a patient with repaired TOF with no residual intracardiac shunts is expected to be fully saturated, and a finding of desaturation likely represents a complication that warrants expedient investigation. This clinical scenario is a frequent one; a patient with a specific cardiac diagnosis, despite having undergone a successful correction, continues to be incorrectly presumed to have ongoing physiologic perturbation of the unrepaired lesion. Further, it is important to understand whether previous cardiac intervention resulted in complete correction of the lesion or only palliation.

Anesthesia Pitfalls

Providing physiologic anesthetic management can be challenging in patients with CHD, especially in situations such as single-ventricle palliation, unrepaired CHD, chronic cyanosis, and residual intracardiac pathology. Standard anesthetic management paradigms may be completely inappropriate and potentially disastrous in the setting of complex CHD. A thorough understanding of the patient's anatomy is mandatory, along with knowledge of the potential for unexpected response to anesthetic agents and ventilator settings. The field of pediatric and congenital cardiac anesthesia has evolved relative to this specific clinical need; the text by Andropoulos, Mossad, and Gottlieb[14] is an excellent resource.

Several points concerning anesthesia management warrant discussion. The first is vascular access for intraoperative and postoperative management. In patients with complex CHD, especially patients who have undergone previous complex surgical and catheterization procedures, obtaining appropriate vascular access may be challenging. Typically, a large-bore, multilumen central venous line is necessary for appropriate resuscitation and monitoring of right-sided filling pressures. In some patients, the placement of a thermodilution pulmonary artery catheter (oximetric) must be considered because one cannot presume that right-sided filling pressures correlate well with left heart volume or functional status (e.g., after a Fontan operation). Options for central access mirror those of non-CHD patients and include percutaneous internal jugular or subclavian routes with a secondary option of common femoral access to the inferior vena cava (IVC). However, access may be difficult in the setting of previous catheterization or venous reconstruction; this situation may be addressed with the aid of ultrasound-guided catheter placement, which has become a standard in many cardiac operating rooms. Arterial access for continuous blood pressure monitoring and sampling is important for many patients. Percutaneous radial arterial cannulation can be readily achieved in most patients; however, upper extremity blood pressure values may be factitiously altered by previous systemic-to-pulmonary artery shunts, previous aortic arch surgery (especially coarctation), and abnormalities of vascular origin (e.g., aberrant subclavian origin from the descending aorta).

Ventilator management in the perioperative setting of CHD requires special understanding. In settings of large potential left-to-right shunts (e.g., unrepaired VSDs), hyperventilation and hyperoxygenation promote excessive pulmonary blood flow and potentially diminish systemic cardiac output. Positive pressure ventilation, particularly positive end-expiratory pressure, negatively influences hemodynamics in many patients, especially in palliated patients with a single ventricle and passive cavopulmonary flow after the Fontan procedure. Early extubation in these patients can be done to limit the deleterious effects of positive end-expiratory pressure on the Fontan circulation. Data have shown that early extubation is feasible and safe, improves outcomes, and reduces overall hospital costs for these patients.[15] Finally, pharmacologic manipulation of systemic and PVR and cardiac performance are important adjuncts in the perioperative management of patients with CHD. In general, a low-dose infusion of epinephrine 0.05 mcg/kg/min (0.02–0.05 mcg/kg/min) with the addition of a phosphodiesterase inhibitor is an effective pharmacologic cocktail to promote a cardiac inotropic state, lower systemic and PVR, and limit tachycardia. Dopamine, vasopressin, sodium nitroprusside, and nitroglycerin are other frequently used agents. Appropriate perioperative analgesia and sedation are also important aspects of the patient's management.

Neurologic Outcomes

With expectations of almost 100% survival after surgery for CHD, emphasis has been placed on the long-term neurologic outcomes and quality of life of these patients. The potential for neurologic insult in children after CHD arises from the nature of their disease (e.g., cyanotic defects, low-cardiac-output state, genetic syndromes, effects of cardiopulmonary bypass, circulatory arrest). Evidence also suggests that patients with CHD may be genetically predisposed to neurologic insult. Gestational age has been found to be an important factor to consider in the optimization of neurologic outcomes.[16]

LESION OVERVIEW

Defects Associated With Increased Pulmonary Blood Flow

Persistent Arterial Duct (Patent Ductus Arteriosus)

A persistent arterial duct, or PDA, is a frequently encountered congenital cardiac condition. PDA is found in 1 in 2000 term neonates but has significantly increased incidence in preterm neonates, with an incidence of 40% in infants with birth weights less than 2000 g and 80% for less than 1200 g. The arterial duct is necessary during gestation to shunt right ventricular blood away from the unventilated pulmonary vasculature; ductal flow is from the pulmonary artery to the aorta during gestation. At delivery, after the first breath of the neonate, ductal flow reverses and becomes left to right in most individuals. Over the first several hours to days of postnatal life, the PDA closes spontaneously and is completely closed in most infants by 2 to 3 weeks of age.

In the absence of other congenital cardiac lesions, a PDA becomes pathologic related to its presence and the degree of left-to-right shunting. A PDA may be present in association with other structural cardiac conditions and may sometimes be necessary for systemic or pulmonary blood flow. The amount of shunting produced relates to the size and geometry of the duct and the PVR. A PDA may be responsible for a large Qp/Qs ratio and result in pulmonary overcirculation, left heart volume overload, and congestive heart failure (CHF). A large unrestricted PDA is associated with pulmonary hypertension; if left untreated, this proceeds to irreversible pulmonary vascular disease (Eisenmenger syndrome), which ultimately proceeds to pulmonary and right heart failure, treatable only by pulmonary transplantation. Even with a small, pressure-restrictive PDA, there is an ongoing risk for pulmonary congestion and left heart volume overloading; endocarditis is always of concern, even for small PDAs. Ligation or closure is recommended for all PDAs.

The gold standard of therapy for closure of PDA is surgery, usually accomplished through a left posterolateral thoracotomy using ductal division, ligation, or clipping (Fig. 113.6). Surgery needs to be a low-risk procedure associated with minimal potential for persistence of the PDA. Nonetheless, the invasive nature of this proven method has led to the development of alternative strategies for ductal occlusion. From a surgical perspective, many PDAs are amenable to thoracoscopic clipping through very small port incisions; robot-assisted PDA occlusion has been performed in many patients, with good results.[12] Medical treatment with indomethacin (0.1 mg/kg for <1 kg, 0.2 mg/kg ≥ 1 kg on day 1, then 0.1 mg/kg daily for days 2–7 oral or IV over 1 hour) can be attempted in a neonate but carries risk of necrotizing enterocolitis, intracranial hemorrhage, and renal toxicity. An alternative strategy involves acetaminophen 15 mg/kg every 6 hours for 3 to 7 days. Reported success rates of medical intervention vary significantly. At the present time, most PDAs are occluded in the cardiac catheterization laboratory using occlusive devices. Even the repair of large defects in small infants has been successfully addressed. The long-term effects of the devices remaining in the vascular tree are not fully understood yet; however, successful device closure appears to be an extremely effective, safe, and durable therapy. Recently, catheter-based devices have been approved for PDA occlusion on preterm infants as small as 700 g.

A PDA in an adult patient can be challenging. As noted, a long-standing large PDA may be associated with pulmonary vascular disease. A right-to-left shunt in a PDA is cause for significant concern and warrants further investigation with concern for significantly elevated PVR. In adults with PDAs, the ductus wall may calcify, making an attempt at ligation or division hazardous. In these patients, ductal occlusion may require resection of the adjacent descending aorta with patch grafting or short-segment graft replacement (e.g., Dacron).

Aortopulmonary Septal Defect (Aortopulmonary Window)

An aortopulmonary septal defect is a communication between the ascending aorta and, usually, the main pulmonary artery. This is a rare defect comprising 0.1% to 0.6% of CHD. This lesion results from the failure of complete separation of the embryologic common arterial trunk into the aorta and pulmonary artery. Defects are classified by their location: type I is proximal, just above the aortic sinuses; type II is more distal on the ascending aorta and often involves the origin of the right pulmonary artery; and type III is more distal and associated with a separate origin of the right pulmonary artery from the aorta (Fig. 113.7). An aortopulmonary septal defect may occur in isolation or in association with other conditions, including interrupted aortic arch (IAA) and

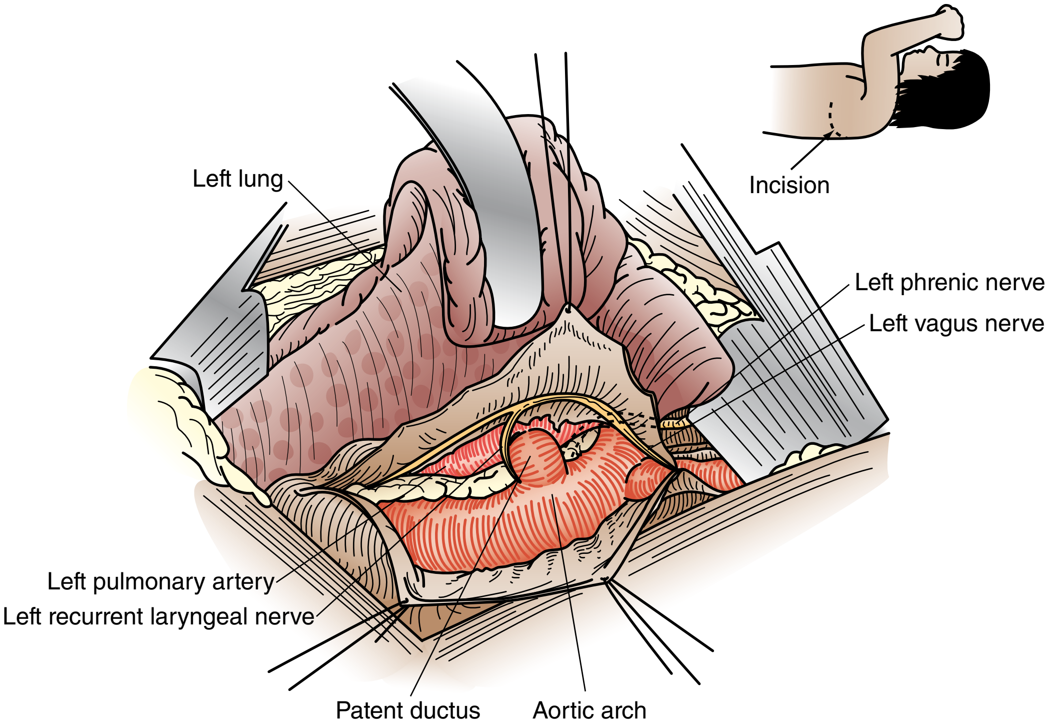

FIGURE 113.6 Anatomic relationships of a patent ductus arteriosus exposed from a left thoracotomy. (From Castaneda AR, Jones RA, Mayer JE, Jr, et al. Patent ductus arteriosus. In: *Cardiac Surgery of the Neonate and Infant*. Philadelphia: Saunders;1994.)

anomalous origin of a coronary artery. Defects are typically large and responsible for a large left-to-right shunt with systemic pulmonary artery pressures. Children with this defect typically present with CHF, failure to thrive, and frequent respiratory infections. Echocardiography, MRI, or cardiac catheterization may be used to make the diagnosis.

The gold standard for repair of aortopulmonary septal defects is surgical closure. Case reports of transcatheter closure exist; however, this is a technically challenging feat without known long-term durability.[17] A small defect may be ligated through a thoracotomy or median sternotomy approach, but this method is not recommended because of significant risk for rupture or incomplete closure. Surgical closure is accomplished with cardiopulmonary bypass support. Options for closure include complete division and separate patch repairs of the great vessel defects or a sandwich type of closure, using a patch to construct a common intervening wall; both methods are effective (Fig. 113.8).

Atrial Septal Defect

An isolated ASD is one of the most common congenital cardiac lesions, occurring in 13 of every 10,000 live births. The most frequently encountered ASD relates to a defect in the interatrial wall, as defined by the fossa ovalis. The defect develops as the result of incomplete closure of the embryologic patent foramen ovale; the defect is a result of incomplete closure of the septum primum. Although the terminology can be confusing, these defects are typically termed *secundum atrial septal defects*. They manifest in a wide variety of configurations, ranging from single small defects to multiple fenestrations to complete absence of the septum primum. The confines of the defect may extend from the IVC orifice up to the superior atrial wall adjacent to the aortic root (Fig. 113.9).

The primary pathophysiologic derangement in ASDs relates to a significant left-to-right shunt in the setting of normal PVR. However, even in the setting of a normal PVR, patients with ASDs are capable of transient right-to-left shunting, particularly during times of increased intrathoracic pressure. The effects of chronic, large left-to-right shunting (in some patients producing a Qp/Qs >3:1) include right heart volume overloading and enlargement. Most children are not overtly symptomatic but may exhibit some degree of exercise intolerance or frequent respiratory tract infection. Symptoms typically become more prevalent in adulthood and include dyspnea on exertion, palpitations, and, ultimately, evidence of right heart failure. Pulmonary vascular disease is not a typical finding in secundum ASDs, but one may demonstrate an ASD in a patient with primary pulmonary hypertension. A rare form of presentation relates to the potential of right-to-left shunting at the atrial level; the ever-present risk for paradoxical embolus and cerebrovascular accident must be considered when recommending ASD closure.

Most centers recommend ASD closure in patients before school age. Since the late 1950s, the standard therapy for ASDs has been surgical closure using cardiopulmonary bypass support. The defect is closed using direct suture closure, autologous pericardium, or prosthetic patch material (Fig. 113.10). This is an effective method with a low associated perioperative risk, including the virtual absence of residual or recurrent defects.[18] Minimally invasive techniques for ASD closure have also gained popularity, with good safety profiles and outcomes.[19]

The potential for closing defects using nonsurgical methods has led to the development of catheter-based therapies, which are now being widely applied to large numbers of patients worldwide for the treatment of ASD. Currently, upward of 60% of ASD interventions are catheter based.[20] The most commonly used device is the Amplatzer septal occluder device (St. Jude Medical,

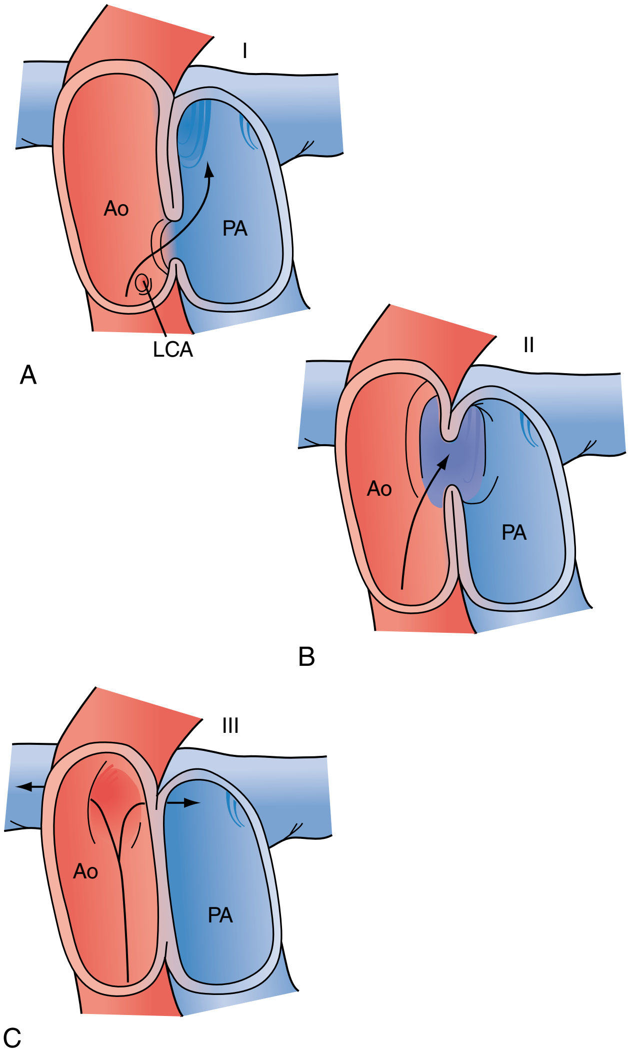

FIGURE 113.7 Native anatomy and classification of aortopulmonary septal defect. (A) In type I, the communication is between the ascending aorta *(Ao)* and the main pulmonary artery *(PA)* on the posterior medial wall of the ascending aorta. The left main coronary artery *(LCA)* orifice may be close to the defect. (B) In type II, the defect is more cephalic on the ascending aorta. (C) In type III, the defect is more posterior and lateral in the aorta. The communication is with the right pulmonary artery, which may be completely separate from the main pulmonary artery. (Adapted from Fraser CD. Aortopulmonary septal defects and patent ductus arteriosus. In: Nichols DG, Ungerleider RM, Spevak PJ, et al, eds. *Critical Heart Disease in Infants and Children*. Philadelphia: Mosby; 2006:664-666.)

St. Paul, MN), made of nitinol metal mesh, which is placed percutaneously and delivered with echocardiographic and fluoroscopic guidance. Reports indicated an acceptable procedure-related complication rate and successful closure rate.[21] However, the long-term effects of having such a device in mobile cardiac structures are not fully understood. More recent reports have documented an alarming incidence of device erosion through the atrial wall and into the adjacent ascending aorta as well as disruption of the conduction system.[22,23] A case report showing severe endocarditis involving a previously placed Amplatzer ASD device has highlighted the need for ongoing observation of the long-term consequences of placing large prosthetic devices into the circulation.[24]

Sinus venosus ASDs occur as the result of embryologic malalignment between the superior vena cava (SVC) or IVC. These defects are not associated with the fossa ovalis and are frequently associated with partial anomalous pulmonary venous return. A superior sinus venosus ASD occurs high in the atrium, near the orifice of the SVC. This lesion is frequently associated with anomalous drainage of a portion of the right lung to the SVC. An inferior sinus venosus ASD is located low in the atrium, often extending into the IVC orifice. This lesion is typically associated with anomalous pulmonary venous drainage of the entire right lung to the IVC (potentially intrahepatic); pulmonary sequestration and an abnormal systemic artery perfusing the right lower lobe, with origin from the abdominal aorta, may also be present. In patients with total anomalous pulmonary venous return (TAPVR) to the IVC, the anomalous pulmonary vein may be obvious on a plain chest radiograph and has been described as appearing like a saber (scimitar syndrome), first described by Neill and colleagues.[25]

Surgery for sinus venosus ASDs is recommended for the same pathophysiologic reasons surgery is recommended for secundum ASDs. The repair is not amenable to catheter techniques, and surgery is more complicated than for an isolated secundum ASD. Superior sinus venosus defects with partial anomalous pulmonary venous return to the SVC may be treated with an intracardiac patch baffle; however, in the setting of high drainage of the anomalous pulmonary veins, an SVC translocation operation (Warden procedure) may be necessary. Surgery for an inferior sinus venosus ASD with a scimitar vein can be more complicated, potentially involving the need for a patch baffle within the intrahepatic IVC, which may require periods of hypothermic circulatory arrest.

Ventricular Septal Defect

A VSD is a pathologic communication involving a defect in the interventricular septum. Isolated VSD is present in 0.3% of newborns. Defects are classified in terms of their location and surrounding structures. Patients may be entirely asymptomatic, depending on the size and location of the VSD, along with associated lesions and PVR. In the setting of otherwise normal cardiac morphology and appropriate PVR, the net shunt in patients with VSD is left to right; the Qp/Qs depends on the size of the defect and pulmonary resistance. Large defects result in large shunts, high right ventricular and pulmonary artery pressures, significant pulmonary overcirculation, CHF, and left heart volume overload. In these settings, unrestrictive pulmonary blood flow exposes the patient to the risk of pulmonary vascular disease and Eisenmenger syndrome.

The ventricular septum can be best thought of in terms of the pathway of blood and associated cardiac anatomy. Thus, the right ventricular aspect of the septum has an inlet portion; midmuscular portion; apical, posterior, anterior, and outlet portions; and subaortic portion. This knowledge aids in the classification of VSDs. Furthermore, defects are understood relative to their embryologic origins and have varying propensities for spontaneous decreases in size or closure.

Perimembranous Ventricular Septal Defect

A perimembranous VSD occurs as a defect in the membranous portion of the interventricular septum; its associated margins include the annulus of the tricuspid valve, the muscular septum, and potentially the aortic annulus. The defects may be large and have associated prolapse of the noncoronary or right coronary aortic valve cusps. Perimembranous VSDs exhibit a potential for spontaneous closure, particularly small defects manifesting early in childhood.

Muscular Ventricular Septal Defect

Muscular VSDs occur in all aspects of the muscular interventricular septum. Margins of these defects are entirely muscle. The lesions may be isolated or involve multiple openings in the septum (so-called Swiss cheese septum). Small defects have great potential for regression or spontaneous closure.

Subarterial (Supracristal or Outlet) Ventricular Septal Defect

Subarterial VSDs occur in association with the annulus of the aortic valve, pulmonary valve, or both. The defects are almost always associated with significant prolapse of the adjacent aortic valve cusp, usually the right coronary cusp, which may lead to significant cusp distortion, aortic valve insufficiency, and cusp perforation. The only mechanism for spontaneous closure of these defects relates to the cusp prolapse and valve distortion and is generally not complete or a favorable arrangement. All these defects are surgically closed because of the ongoing risk of aortic valve injury (Fig. 113.11).

The indications for surgery to close VSDs relate to the size of the VSD, degree of shunting, and associated lesions. Small infants presenting with large VSDs, refractory heart failure, and large shunts undergo surgical closure of the defects in the newborn period, regardless of age or size. Other defects are addressed based on the ongoing concerns of left-to-right shunting, aortic valve cusp distortion, and risk for endocarditis. Asymptomatic patients with evidence of significant shunts and cardiomegaly are proposed for surgical therapy. Prophylactic closure of small defects in asymptomatic patients with normal cardiac size and function is advocated by some surgeons because of the lifelong risk for endocarditis and comparatively low risk for surgery.

Percutaneous VSD closure is an acceptable alternative to surgical closure of VSDs with very high procedural success.[26] Despite this, the complex relationship of many defects, including close association with the aortic valve and cardiac conduction tissue, makes the existing technology less than ideal. At the present time, surgery remains the primary mode of therapy for VSD closure. Defects are approached with the aid of cardiopulmonary bypass support and may be closed with various materials, including autologous pericardium (our preference), Dacron, polytetrafluoroethylene, and homograft material. Surgical closure of VSDs is a low-risk procedure with a high expectation of complete closure. Challenging anatomic situations, such as Swiss cheese septum or multiple apical muscular VSDs, may be initially palliated by limiting pulmonary blood flow with a pulmonary artery band and deferring corrective surgery to later in life when the child is larger.

Atrioventricular Septal Defect (Atrioventricular Canal Defect)

Atrioventricular septal defects (AVSDs) are a complex constellation of cardiac lesions involving deficiency of the atrial septum, ventricular septum, and A-V valves and occur in approximately 1 in every 2100 live births. This lesion results from an embryologic maldevelopment involving the endocardial cushions; thus, the term *endocardial cushion defect* is often applied. AVSDs may be partial, involving no ventricular-level component; intermediate or transitional, involving a small restrictive VSD; or complete, involving a large nonrestrictive VSD. The A-V valve tissue is always abnormal in AVSD, although there is great individual variability in terms of the severity of the valvular malformation and valve function. Complete AVSDs are frequently seen in patients with trisomy 21 but also occur in patients with normal chromosomes. The morphology of the septal defects in this condition is different from that previously discussed. The ASD in this defect is termed a *primum ASD* and is distinctly separate from the fossa ovalis. There is displacement of the A-V node and bundle of His to the inferior aspect of the primum defect and A-V junction, a feature of critical importance during surgical repair. Patients with AVSD have an *inlet VSD,* which may extend into the subaortic region and have a component of septal malalignment. The chordal support of the A-V valves has a variable relationship to the interventricular septum. The relationship of the chordal support and superior bridging component of the left A-V valve has been used to classify complete AVSD, as described by Rastelli and associates[27]: type A, with superior leaflet and chordal support committed to the left side of the ventricular septum; type B, with straddling and shared chordal support; and type C, with a floating left superior leaflet component and chordal support on the right side of the ventricular septum (Fig. 113.12).

Patients with complete AVSD typically present in infancy with large left-to-right shunts, cardiomegaly, and CHF. Without surgical treatment, patients exhibit severe failure to thrive, a susceptibility to severe respiratory infections, and potential for early development of pulmonary vascular disease. Surgical repair is recommended in infancy (usually before 6 months of age) but may be necessary in the newborn period for neonates with refractory heart failure, especially in association with aortic arch anomalies. Patients with partial or intermediate defects may have the surgery deferred until later in childhood, depending on the degree of atrial level shunting and the presence of A-V valve regurgitation. AVSD may also manifest in unbalanced forms with dominance of right-sided or left-sided components. In severely affected individuals, biventricular repair is not feasible, and patients are managed along a single-ventricle pathway. AVSD may also be found in association with TOF; this combination is associated with cyanosis, and repair is more challenging than for either condition considered in isolation.

Surgery is the primary mode of therapy for patients with AVSD. Operative goals include complete closure of ASDs and VSDs and effective use of available A-V valve tissue to achieve valve competence. As noted, the inferiorly displaced conduction tissue must be protected to avoid the complication of surgically induced A-V block (Fig. 113.13). Surgical intervention is performed with the use of the cardiopulmonary bypass machine. The atrial and ventricular septal components are closed with a common patch (single-patch method) or separate patches (two-patch technique). We believe the two-patch method to be superior in preserving A-V valve tissue (Fig. 113.14).[28] The critical

component of the repair lies in the valve repair; typically, after suspending the valve tissue to the reconstructed septum, the line of coaptation between the superior and inferior leaflet components (cleft) is closed; however, care must be exercised to avoid valvular stenosis.

Perioperative care is predicated on an accurate and hemodynamically favorable repair. Patients with long-standing pulmonary overcirculation may have a potential for early perioperative pulmonary hypertensive crisis. This condition may require therapy, including oxygen, optimization of fluid balance, continuous sedation, hyperventilation, and, possibly, inhaled nitric oxide.

Adult Patients With Atrioventricular Septal Defect

Numerous patients with partial or transitional AVSD survive well into adulthood without surgery. These patients have variable presentations but may exhibit severe exercise intolerance; evidence of right heart dysfunction; some elevation of PVR; and, possibly, atrial dysrhythmias, including atrial fibrillation. In patients with late presentation of AVSD, cardiac catheterization is often recommended to rule out occult coronary artery lesions and evaluate PVR. Nonetheless, in the absence of obvious surgical contraindication, surgery is recommended for adults with unrepaired AVSD to eliminate the chronic left-to-right shunt and repair the typically insufficient A-V valves.

Other patients present well into adulthood with previously repaired AVSDs. These patients may have a widely disparate constellation of findings, including atrial and ventricular dysrhythmias, valvular insufficiency or stenosis, and right heart dysfunction. In many of them, secondary reparative surgery may become necessary. Furthermore, in the setting of a patient with remotely repaired AVSD requiring noncardiac surgery, potential ongoing hemodynamic concerns that would affect the perioperative course must be expected.

Persistent Arterial Trunk (Truncus Arteriosus)

Truncus arteriosus, or persistent arterial trunk, results from failure of separation of the embryonic arterial trunk and semilunar valves and occurs in approximately 1 in 10,000 live births. It is almost always associated with a large nonrestrictive perimembranous VSD and is associated with varying degrees of truncal override of the interventricular septum, including 100% association of the trunk with the RV. The condition is classified by the relationship of the origins of the pulmonary arteries. In type I truncus arteriosus, there is a demonstrable common main pulmonary artery with subsequent origins of the branch pulmonary arteries; in type II truncus arteriosus, the branch pulmonary arteries arise closely, but separately, from the trunk; in type III truncus arteriosus, the branch pulmonary arteries are widely separated in origin on the ascending aorta; and in type IV truncus arteriosus, no pulmonary arterial branch arises from the common trunk. Type IV truncus arteriosus is now recognized as a form of pulmonary atresia with VSD (Fig. 113.15).

In contrast to patients with aortopulmonary septal defects, patients with truncus arteriosus have a single outlet valve of highly variable morphology. The valve may have a normal appearance, with three well-formed and distinct cusps similar to those of a normal aortic valve. In other patients, the truncal valve may be severely malformed, with multiple cusps, dysmorphic leaflets, and abnormal commissural relationships. The truncal valve morphology and function have significant bearing on patient symptoms and the difficulty of surgery. Patients with truncus arteriosus frequently have coronary ostial abnormalities, including juxtacommissural origin

and intramural course. There is an associated interruption of the aortic arch in 25% of newborns presenting with truncus arteriosus. Abnormalities of thymic genesis, T-cell function, and calcium homeostasis may frequently be seen in this group of patients in association with a chromosome 22 deletion (DiGeorge syndrome).

Patients with truncus arteriosus present in the newborn period with unrestricted pulmonary blood flow and systemic pulmonary artery pressure. With the expected postnatal decrease in PVR, massive pulmonary overcirculation, and CHF, patients may exhibit a wide pulse pressure because of diastolic runoff of blood into the pulmonary vasculature. This situation is further exacerbated in the setting of significant truncal valve insufficiency, resulting in poor systemic perfusion and cardiovascular collapse. Some infants can be initially managed with medical decongestive therapy (e.g., diuretics, angiotensin-converting enzyme inhibitors, and digoxin) and fortified nutritional support (through gastric intubation); however, this is a precarious arrangement. In the few individuals who survive infancy, irreversible pulmonary vascular disease develops rapidly, and patients become inoperable. In other patients, refractory CHF results in poor weight gain, respiratory insufficiency, and susceptibility to infection. The profound hemodynamic compromise places many newborns with unrepaired truncus arteriosus at high risk for necrotizing enterocolitis. Patients with truncus arteriosus and IAA have ductal-dependent systemic blood flow and are dependent on intravenous PGE1 to maintain ductal patency until they undergo repair. Given these considerations, it is recommended that most newborn patients undergo repair in the first several weeks of life.

The surgical repair is performed on cardiopulmonary bypass support. Components of the repair include division of the common trunk and reconstruction of confluent central branch pulmonary arteries. The large VSD is closed with a patch, typically through a right ventriculotomy. In patients with an abnormal, insufficient truncal valve, a valve repair may be necessary. It is unusual to have to replace the truncal valve at the initial operation; most valves can be at least partially repaired to provide the patient with an adequate aortic valve. Right ventricle–pulmonary artery continuity then must be established. Most surgeons prefer to interpose a valved conduit between the right ventriculotomy and pulmonary artery bifurcation (Fig. 113.16).

Conduits are limited and include homografts (pulmonary artery or aorta, valved) or heterografts (bovine or porcine). Experience with a commercially available, glutaraldehyde-preserved, bovine jugular vein valved conduit (Contegra; Medtronic, Minneapolis, MN) had been encouraging. However, there is a concerning increased incidence of endocarditis with Contegra valved conduits compared with other conduits, including homografts and heterografts.[29] An emerging option is the partial heart transplant or living homograft. In this setting, the semilunar valves ± root complexes from a donor heart that has gone unmatched for conventional cardiac transplant are procured and used similarly to a cryopreserved homograft. The theoretical benefit of this procedure is the potential for the living homograft to grow with the patient, potentially obviating the need for repeat interventions. Uncertainty remains around the need, type, and duration of immunosuppression and the mid- and long-term outcomes and durability of the transplanted valve.[30] Successful repair of truncus arteriosus in infants using a direct hooded anastomosis between the pulmonary artery bifurcation and right ventriculotomy has also been reported.[31] No option available at the present time offers patients the lifetime solution of a connection capable of somatic growth along with a competent, durable pulmonary valve. Thus, it is expected that all infants undergoing successful truncus repair will require multiple subsequent cardiac surgeries as they outgrow their current RV–pulmonary artery conduit. Experience with a percutaneously delivered, catheter-mounted pulmonary valve has been encouraging as an interim solution for these patients in an effort to limit the number of required cardiac reoperations.

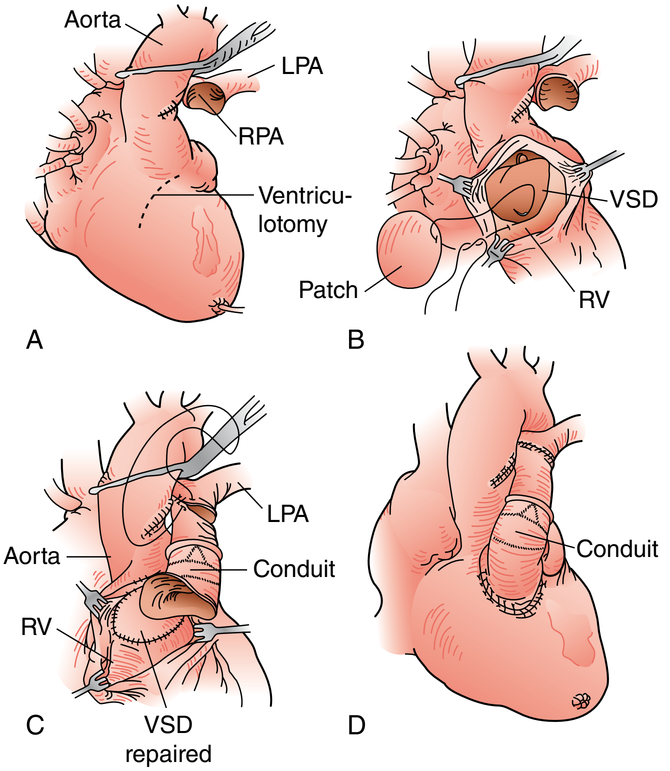

FIGURE 113.16 Surgical repair of truncus arteriosus. (A) The origin of the truncus arteriosus is excised, and the truncal defect is closed with a direct suture. The incision is made high in the right ventricle *(RV)*. (B) The ventricular septal defect *(VSD)* is closed with a prosthetic patch. (C) Placement of a valved conduit into the pulmonary arteries. (D) Proximal end of conduit is anastomosed to the RV. *LPA*, Left pulmonary artery; *RPA*, right pulmonary artery. (From Wallace RB. Truncus arteriosus. In: Sabiston DC, Jr, Spencer FC, eds. *Gibbons Surgery of the Chest*. 3rd ed. Philadelphia: Saunders; 1976.)

A growing number of adults have survived childhood truncus arteriosus repair. All these patients require diligent longitudinal cardiology surveillance, and many will require reoperation. Issues of concern include late ventricular dysrhythmias, often related to surgical scarring from the previous right ventriculotomy; branch pulmonary artery stenosis; stenosis or insufficiency of the RV–pulmonary artery conduit; truncal valve insufficiency; and right ventricular dysfunction.

Abnormalities of Venous Drainage

Total Anomalous Pulmonary Venous Return

TAPVR results from embryonic failure of connection of the fetal pulmonary venous sinus to the left atrium and occurs in 1 in every 10,000 live births. This fatal condition has a spectrum of clinical presentations and may be associated with additional complex structural cardiac disease, including a single ventricle. In TAPVR, pulmonary venous return may take one of several pathways to return eventually to the right heart. Initial survival is predicated on an unobstructed pathway and unrestricted atrial-level communication so that sufficient intracardiac mixing affords the patient adequate systemic oxygenation. Patients with TAPVR are desaturated to varying degrees, depending on the adequacy of the anomalous pathway, atrial mixing, and pulmonary function. The abnormal venous connection drains in several typical patterns.

In supracardiac TAPVR, the pulmonary veins drain to a vertical vein, which courses cephalad to join a systemic vein. In the most common variation, the vertical vein courses anterior to the left pulmonary artery to join the left innominate vein. This vein may course posterior to the left pulmonary artery, resulting in compression of the pulmonary venous pathway between the left pulmonary artery and left mainstem bronchus (so-called pulmonary artery vise). The vertical vein may also join the SVC or azygos vein. In intracardiac TAPVR, the pulmonary veins drain into the coronary sinus and, in most cases in which the coronary sinus is intact, into the right atrium. This variant is rarely obstructed and may not be diagnosed until later in life in some patients. In infracardiac TAPVR, the vertical veins descend in a caudal direction through the diaphragm to join the embryologic ductus venosus and then through the liver to join the IVC. This variation is almost always obstructed at some level (Fig. 113.17). In mixed TAPVR, the pulmonary venous pathway drains in several pathways to reach the heart. Frequently, in mixed TAPVR, one or several pulmonary veins connect to the SVC, with others draining to an infracardiac or supracardiac connection.

Obstructed total anomalous pulmonary venous return. Obstructed TAPVR is one of the few true surgical emergencies in congenital heart surgery. When the condition is suspected, it is diagnosed with transthoracic echocardiography. Obstructed TAPVR occurs when one of the drainage patterns noted earlier is obstructed, resulting in severe pulmonary venous hypertension. Secondary effects include pulmonary edema, pulmonary artery hypertension, and profound hypoxemia. Interstitial pulmonary emphysema and frank pneumothorax may develop while attempting vigorous ventilatory support in profoundly desaturated children. Patients with obstructed TAPVR may present within hours of birth in extremis and do not respond to resuscitative efforts. The only useful therapy is rapid surgical repair, regardless of the severity of the patient's preoperative status.

For other forms of TAPVR, elective surgical repair is recommended after the condition is diagnosed. Occasionally, the diagnosis is not made until later in childhood in patients with an unobstructed vertical vein and widely patent atrial communication. These patients undergo elective repair to relieve cyanosis, intracardiac mixing, and right heart volume overload.

Surgical repair of TAPVR requires cardiopulmonary bypass support; occasionally, periods of profound hypothermia and circulatory arrest are necessary. The principles of repair include identification of the pulmonary venous confluence and individual pulmonary veins. An anastomosis is constructed between the venous confluence and left atrium using a superolateral approach, with the heart reflected to the patient's right, or an incision directly through the interatrial septum and corresponding region of the posterior right atrial wall. The ASD and PDA that are typically present are closed as well (Fig. 113.18).

Cor triatriatum. Cor triatriatum is a rare condition accounting for ~0.1% of all congenital heart defects in which the pulmonary veins enter a chamber posterior to the left atrium with a small connection to the right or left atrium. These patients exhibit evidence of pulmonary hypertension and variable desaturation. Surgical decompression is necessary to relieve the pulmonary venous obstruction; this is accomplished by resection of the

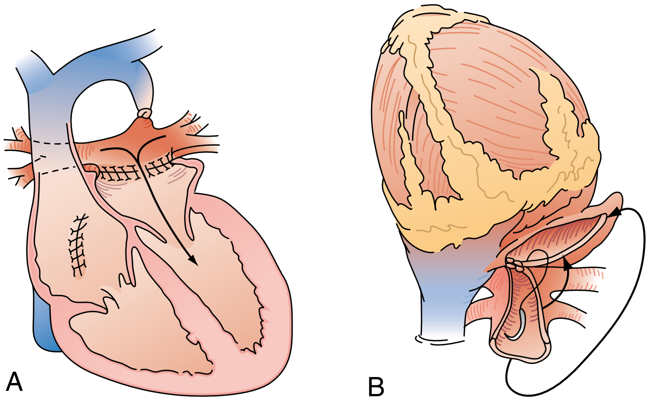

FIGURE 113.18 (A) Repair of supracardiac total anomalous pulmonary venous connection (TAPVC) through a superior approach. (B) Repair of infracardiac TAPVC. Elevating the apex of the heart to the right side exposes the left atrium and pulmonary confluence. Anastomosis is created as shown. (From Lupinetti FM, Kulik TJ, Beekman RH, et al. membrane between the pulmonary venous chamber and left atrium.

A dreaded consequence of TAPVR occurs when there is a progressive, malignant sclerosing process involving the individual pulmonary veins. This process may be initiated by inaccurate surgery resulting in obstruction of the venous confluence and individual veins, or it may progress independently of surgical manipulation. It may progress to intrapulmonary pulmonary venous stenoses. A technique to deal with individual pulmonary venous stenoses uses a pedicled flap of adjacent pericardium to augment the pulmonary venous orifices (sutureless technique), but this method is not applicable to all patients with pulmonary venous obstruction. Catheter-based dilation and stenting have been attempted in this setting, with good acute relief of obstruction, but they have a high rate of reintervention and unknown long-term success, with 50% survival at 5 years.[32] In the most severe cases, the only meaningful surgical option is lung transplantation.

Anomalous Systemic Venous Drainage

Congenital abnormalities of systemic venous drainage may occur in isolation or in association with other significant structural cardiac defects. In the setting of an otherwise normal heart, the anomaly is frequently not of physiologic significance. The most common example is a persistent left SVC draining to the coronary sinus. In the absence of an intracardiac communication or unroofing of the coronary sinus, this is of anatomic significance only. In many cases, a persistent left SVC occurs, with absence of a communicating innominate vein. This condition becomes important in situations of mechanical occlusion, which may be seen with trauma or chronic venous intubation with thrombosis. A persistent left SVC is frequently incidentally discovered after placement of a left internal jugular central line, which is apparently found to track into the heart on plain chest radiography. A persistent left SVC becomes more significant in patients requiring intracardiac or extracardiac surgery. If the left SVC drains to an unroofed coronary sinus in a patient undergoing atrial septation, the patient will be profoundly desaturated after surgery. This situation requires reconstruction of the coronary sinus or some other method to reroute the left SVC to the right atrium.

An interrupted IVC usually occurs in association with other structural cardiac disease. The IVC drainage in these settings is to the azygos (azygos continuation) or hemiazygos vein and, ultimately, the SVC. In these patients, the hepatic veins drain into the atrium as a common confluence or as individual veins. The physiologic significance of the interrupted IVC relates to the coexisting cardiac lesion and the necessity of appreciating the abnormality of systemic venous drainage in performing corrective surgery. In patients requiring noncardiac surgery or catheter intervention, the presence of an interrupted IVC is noted when an attempt is being made to pass a venous catheter from the groin into the heart.

Cyanotic Congenital Heart Disease

Tetralogy of Fallot

TOF is a common form of cyanotic CHD occurring in approximately 1 in 2500 live births and is probably the most studied lesion in the era of surgical correction for CHD. Many believe that the Johns Hopkins Hospital was the birthplace of cardiac surgery. Blalock performed the first successful palliative operation for TOF in November 1944, assisted by his laboratory technician, Vivien Thomas.[1] Blalock was encouraged by Taussig, the matriarch of pediatric cardiology (Fig. 113.19). Until more recently, some degree of controversy has surrounded the relative degree of contribution by these three individuals in bringing this historical event to fruition. In actuality, all three were significant participants in this momentous medical advance. While working at Vanderbilt Medical School, Blalock had charged his young and capable laboratory technician, Vivien Thomas, with the development of a surgical model of pulmonary hypertension. Thomas and Blalock developed a method of anastomosing the left subclavian artery to the divided left pulmonary artery in a canine model. Specifically, Thomas worked out the technical details, including crafting the necessary surgical instruments, and mastered the operation. This work did not produce the desired effect; canine PVR is almost infinitely low, and the animals did not develop a hypertensive pulmonary vasculature. Nonetheless, the technique was developed and published approximately 10 years in advance of the clinical application in 1944.

Blalock subsequently became the chair of surgery at Johns Hopkins. Taussig had, by that time, established a reputation as a meticulous diagnostician of complex congenital heart lesions. She had a large clinic of critically ill children with disabling cyanosis—“blue babies.” At her suggestion (and probably her insistence), Blalock was convinced to attempt a surgical palliation for TOF by constructing in a human the subclavian-to-pulmonary artery anastomosis that had been perfected in the research laboratory (Fig. 113.20). Blalock performed the operation in conditions and with instruments that would be considered extremely crude

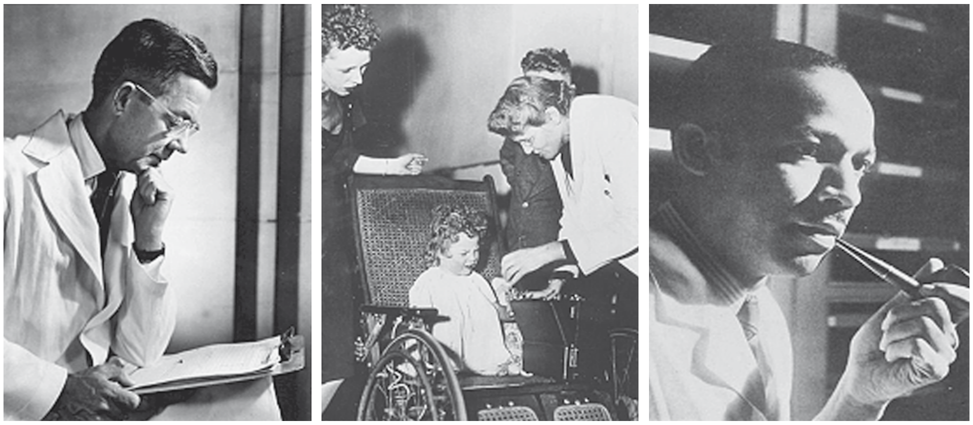

FIGURE 113.19 Drs. Alfred Blalock, Helen Taussig, and Vivien Thomas.

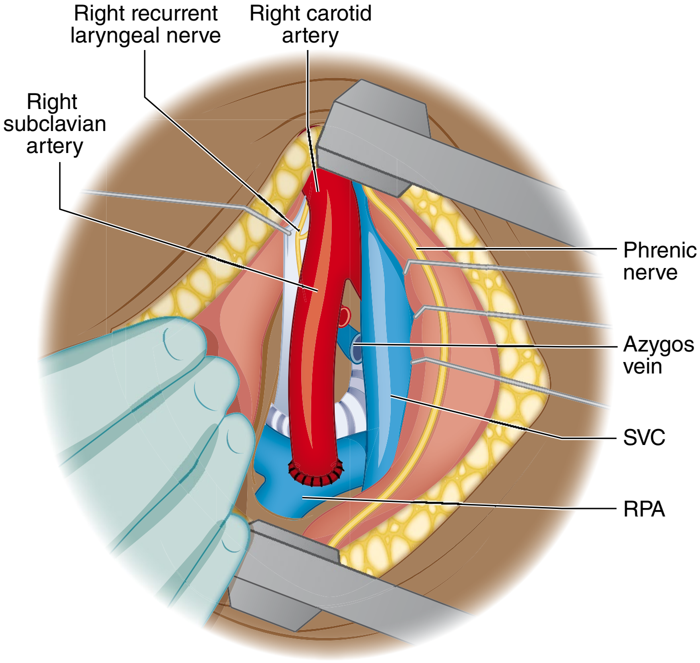

FIGURE 113.20 Classic Blalock-Taussig shunt (right thoracotomy). *RPA,* Right pulmonary artery; *SVC,* superior vena cava. (Modified from Backer CL, Mavroudis C. Palliative operations. In: Mavroudis C, Backer C, Idriss RF, eds. *Pediatric Cardiac Surgery.* Chichester, UK: Wiley; 2012: Chapter 9.)

by today's standards. Thomas stood immediately behind Blalock during that operation and many subsequent cases, providing instruction and encouragement. The clinical success was an earth-shattering event; hundreds of patients subsequently traveled to Johns Hopkins for surgical treatment, and the era of cardiac surgery was ushered in. (These historical accounts are factual, the result of personal interviews with many of those in attendance at that event, including Thomas, Taussig, J. Alex Haller, and Denton Cooley.)

The historical account of the development of the BTT shunt has relevance to the practice of congenital heart surgery today. First, it is important that the facts surrounding this achievement are acknowledged. Second, this remarkably simple concept still remains a frequently applied technique for children with inadequate pulmonary blood flow. Finally, over almost 75 years of treatment of TOF, thousands of patients have been successfully treated, but most are not cured; many require subsequent reoperative cardiac surgery, even after complete repair.

The anatomic hallmark of TOF is anterior malalignment of the infundibular septum, which leaves a deficiency in the subaortic region—a malalignment VSD. This VSD is usually perimembranous, large, and pressure nonrestrictive. The relative degree of malalignment influences the relationship of the aorta to the interventricular septum, producing varying degrees of aortic override. The deviated infundibular septum produces varying degrees of RVOTO. The path of pulmonary blood flow may be impeded at numerous levels, including the infundibulum, pulmonary valve and annulus, and main and branch pulmonary arteries. Secondary right ventricular hypertrophy occurs relative to the degree and duration of the obstruction and is progressive, contributing to the propensity for the lesion to worsen over time (Fig. 113.21).

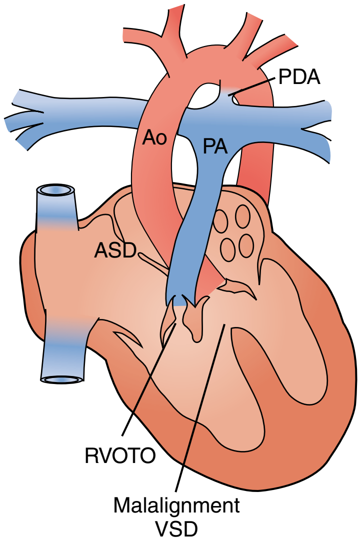

FIGURE 113.21 Anatomy of tetralogy of Fallot. A malalignment ventricular septal defect *(VSD),* aortic override, right ventricular outflow tract obstruction *(RVOTO),* and subsequent right ventricular hypertrophy. *Ao,* Aorta; *ASD,* atrial septal defect; *PA,* pulmonary artery; *PDA,* patent ductus arteriosus. (Adapted from Davis S. Tetralogy of Fallot with and without pulmonary atresia. In: Nichols DG, Ungerleider RM, Spevak PJ, et al, eds. *Critical Heart Disease in Infants and Children.* Philadelphia: Mosby; 2006:756.)

The pathophysiology of TOF relates to shunting of desaturated, systemic venous blood through the VSD to mix with the systemic cardiac output. The greater the degree of obstruction to pulmonary blood flow, the larger the right-to-left shunt and the worse the desaturation. There are several modes of presentation. Newborns with TOF and severe RVOTO may present soon after birth with profound cyanosis; some require PGE1 to maintain ductal patency for adequate oxygenation. At the other end of the spectrum are children with little infundibular obstruction and normal pulmonary valve and branch pulmonary arteries. These patients may have net left-to-right flow through the VSD, occasionally to the extent that they experience pulmonary overcirculation and CHF (so-called pink TOF). Most children present between these extremes; an initially mild to moderate degree of infundibular stenosis progresses over time to become severe with worsening desaturation. A TOF spell occurs when there is an acute change in the cardiac inotropic state, often in the setting of agitation and dehydration. The infundibular stenosis acutely worsens, and patients become profoundly desaturated; this may be an extremely serious event, leading to brain damage or death. Acute treatment modalities include sedation, hydration, systemic afterload augmentation (α-adrenergic agonists), β-blockade to reduce the inotropic state, and endotracheal intubation with supplemental inspired oxygen.

The natural history of untreated TOF is dismal, with most children dying of progressive cyanosis before 10 years of age. Surgery is the mainstay of therapy. Medical and catheter-based therapy may be used to temporize, but TOF is a surgical disease. The principles of surgical correction include patch closure of the VSD and relief of all levels of the RVOTO and pulmonary artery stenosis. The classic method of TOF repair uses a longitudinal incision through the right ventricular outflow tract (RVOT); this provides an excellent transventricular view of the VSD, which is closed with a patch. The pulmonary artery, pulmonary valve, and annulus are incised if stenotic, and then the RVOT is patched. This method was used for many years but has the complicating feature of the long ventriculotomy, with attendant right ventricular dysfunction and often severe pulmonic insufficiency (Fig. 113.22). An alternative method, the transatrial/transpulmonary approach, first proposed by Imai, has gained popularity. In this method, the VSD closure and RVOT resection are accomplished through a right atriotomy via the tricuspid valve. The main pulmonary artery and pulmonary annulus are incised only if stenotic, but there is no transmural infundibular incision. This method is technically more demanding than the classic method but may offer the patient improved long-term right ventricular function (Figs. 113.23–113.25). The approach has been further developed as a right ventricular infundibulum-sparing strategy that focuses on minimizing the right ventricular incision and preserving the pulmonary valve. The right ventricular infundibulum-sparing strategy includes an algorithm for optimal timing of the repair that considers the individual patient's weight, age, and overall clinical picture (Fig. 113.26). Midterm results with this approach have demonstrated preserved right ventricular function.[33]

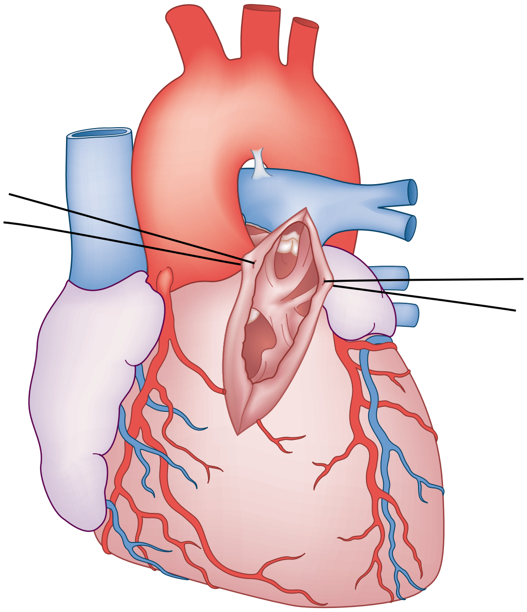

FIGURE 113.22 Long right ventriculotomy in a classic transventricular approach. (From Morales DL, Zafar F, Heinle JS. Right ventricular infundibulum sparing [RVIs] tetralogy of Fallot repair: a review of over 300 patients. *Ann Surg.* 2009;250:611-617.)

The long-term sequelae of TOF repair have been unfolding. For most patients, successful childhood repair of TOF does not translate into a cure. As patients age after TOF repair, long-term complications may develop. Patients with long RVOT incisions (transannular) by necessity have severe pulmonary insufficiency and a noncontractile infundibulum. Over time, the effects of chronic right heart volume overload include right ventricular dilation and decreased function, often with progressive tricuspid insufficiency and elevated central venous pressure. These patients may present with hepatomegaly, peripheral edema, and severe exercise intolerance. Dysrhythmias may frequently occur; patients with large right ventriculotomies develop endocardial scarring, which may be the substrate for ventricular tachycardia. Chronic right atrial dilation may ultimately lead to atrial dysrhythmias, including atrial tachycardia and fibrillation. Relative to these and other potential issues after TOF repair, patients require careful and lifelong medical follow-up. Many need reintervention; this is frequently the case in patients with chronic, severe pulmonary insufficiency, which is indicated when right ventricular dilation and dysfunction become significant. In these patients, placing a competent pulmonary valve is necessary to relieve chronic right ventricular overload. These issues are of particular importance to a patient with repaired TOF presenting for noncardiac surgery. A careful assessment of the patient's cardiac anatomy and function is performed, including echocardiography, Holter or Bardy monitoring, and occasionally, cardiac catheterization.

Pulmonary Atresia and Intact Ventricular Septum

Pulmonary atresia with an intact ventricular septum (IVS) manifests with profound desaturation and ductal-dependent pulmonary blood flow in newborns. The cardiac morphology in this condition varies widely. On the most severe end of the spectrum, patients have very small RVs, tiny tricuspid inlets, and often a RV-dependent coronary circulation. In these cases, the RV must remain hypertensive to provide flow to these segments of the coronary circulation. At the other end of the anatomic spectrum, patients have a relatively normal tricuspid valve and RV. Most patients fall in between these extremes, with some degree of tricuspid valve and RV underdevelopment.

Because patients are ductal dependent at birth, an assessment must be made as to whether the right heart will be capable of ultimately supporting a biventricular circulation. If the coronary circulation is truly RV dependent, decompressing the RV would result in coronary insufficiency. In these situations, a palliative Blalock-Taussig shunt is created in anticipation of promoting the patient down a single-ventricle pathway. In other patients, the atretic pulmonary valve must be opened with percutaneous balloon dilation

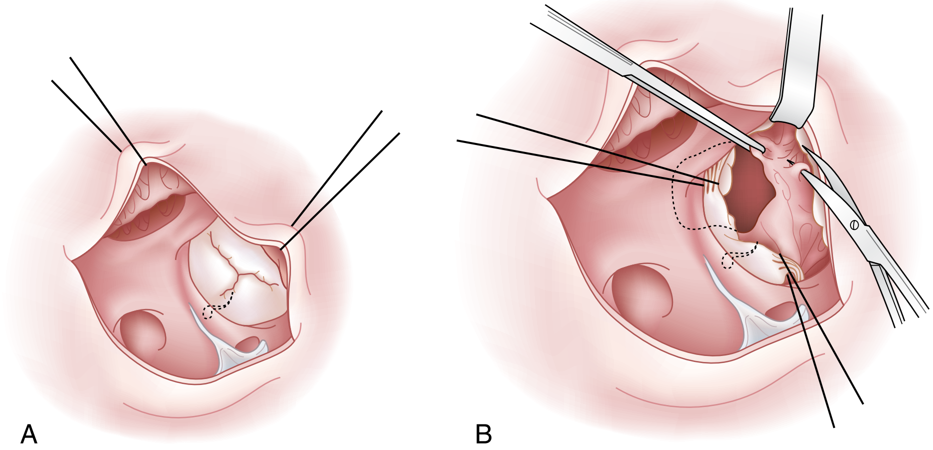

FIGURE 113.23 (A) Surgeon's view through a transatrial incision in the transatrial/transpulmonary approach. (B) Right ventricular outflow tract muscle resection through the right atriotomy. (From Morales DL, Zafar F, Heinle JS. Right ventricular infundibulum sparing [RVIs] tetralogy of Fallot repair: a review of over 300 patients. *Ann Surg*. 2009;250:611-617.)

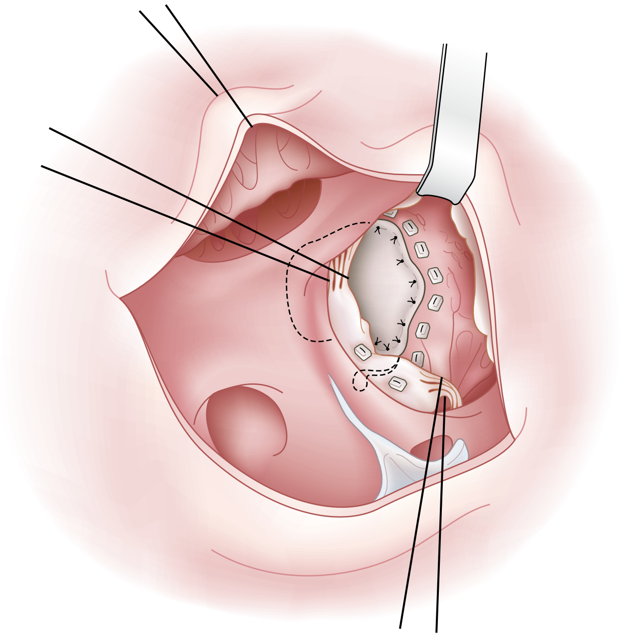

FIGURE 113.24 Ventricular septal defect patch closure with pledgets around the defect and onto the tricuspid valve annulus to avoid the conduction system. (From Morales DL, Zafar F, Heinle JS. FIGURE 113.25 Mini–transannular incision in the transatrial-transpulmonary approach. (From Morales DL, Zafar F, Heinle JS. Right ventricular infundibulum sparing [RVIs] tetralogy of Fallot repair: a review of over 300 patients. *Ann Surg*. 2009;250:611-617.)

or open surgical valvotomy. Over time, the hypertensive, often apparently underdeveloped RV will improve in size and function and become capable of supporting all or a significant proportion of the cardiac output. At initial presentation, many patients have a large patent foramen ovale or ASD; in patients with a restrictive ASD and marginal right heart, an atrial septostomy (balloon) allows for atrial-level right-to-left shunting until the RV improves. Ultimately, if the RV is adequate, the ASD can be closed.

Pulmonary Atresia With Ventricular Septal Defect

Pulmonary atresia with VSD is morphologically similar to TOF, with the exception of an atretic pulmonary valve. Patients may have confluent, normal-sized pulmonary arteries perfused by a PDA. In severe cases, the pulmonary arteries are discontinuous, and the lungs are variably perfused by diminutive native branch pulmonary arteries and muscularized, collateral vessels originating from the descending aorta and brachiocephalic vessels. These major aortopulmonary collateral arteries (MAPCAs) have a propensity to develop severe stenoses as they are exposed to systemic arterial pressure. Many of these MAPCAs eventually occlude at an unpredictable rate during childhood. Because they may provide the only blood supply to some lung segments, patients become progressively desaturated.

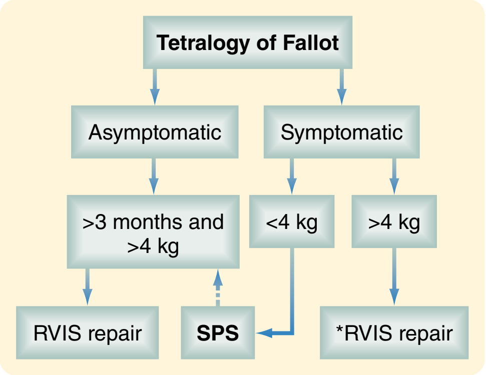

FIGURE 113.26 Algorithm for the right ventricular infundibulum-sparing *(RVIS)* strategy. The goal of this strategy is to minimize the right ventricular incision and preserve the pulmonary valve. It is an individualized approach that considers the patient's weight, age, and overall clinical picture. *SPS,* Systemic-to-pulmonary artery shunt. (From Morales DL, Zafar F, Heinle JS. Right ventricular infundibulum sparing [RVIs] tetralogy of Fallot repair: a review of over 300 patients. *Ann Surg.* 2009; 250:611-617.)

The goal of surgical therapy for pulmonary atresia with VSD is biventricular repair to achieve normal cardiac workload and systemic arterial saturations. In patients with confluent native pulmonary arteries of adequate caliber, the VSD is surgically closed, and a valved conduit (homograft or heterograft) is interposed between the RV and pulmonary bifurcation. In patients with pulmonary atresia with VSD and MAPCAs, the pulmonary arteries must be repaired by connecting the various lung segments into a common trunk through a process termed *pulmonary artery unifocalization*. Depending on the source and size of the MAPCAs and native pulmonary arteries, this may be a challenging surgical procedure, but the goal is constructing a pulmonary tree as close to normal as possible so that biventricular repair is feasible (see earlier).

The long-term issues of repair of pulmonary atresia with VSD are similar to concerns described earlier for TOF. The addition of a RV–pulmonary artery conduit guarantees the need for reoperation because no currently available conduit choice offers the potential for somatic growth or an indefinitely durable valve.

Valvular Pulmonic Stenosis

Patients with isolated valvular pulmonary stenosis are almost always treated in infancy with a percutaneous balloon pulmonary valvotomy. The intermediate-term results of this treatment are good; however, all patients are left with significant pulmonary valve insufficiency and eventually require pulmonary valve replacement.

Conotruncal Anomalies

Transposition of the Great Arteries

Transposition of TGA is a common cyanotic congenital cardiac lesion occurring in 2 to 3 per 10,000 live births. In this section, our discussion relates only to TGA in which there are two good ventricles identified as being capable of independent function as the right and left ventricle. TGA is commonly referred to as *D-TGA,* in relationship to the typically normal D (dextro) ventricular looping that occurs in association with the discordant ventriculoarterial connection and normal A-V connection. TGA occurs in the setting of an IVS (TGA-IVS) or with associated VSD (TGA-VSD). In TGA-VSD, there may be associated aortic arch hypoplasia and coarctation. On the other extreme, there may be severe pulmonic and subpulmonic stenosis (left ventricular outflow tract obstruction [LVOTO]) or even pulmonary atresia (TGA-VSD with pulmonary atresia).

Patients with TGA-IVS typically present in the early newborn period with profound cyanosis associated with normal perinatal PDA closure. In the absence of a significant ASD, the cyanosis is severe and progresses to death if left untreated. Administration of intravenous PGE1 is almost uniformly successful in reestablishing ductal patency to improve the patient's arterial saturation by providing left-to-right shunting and improved pulmonary blood flow.

In most patients, a balloon atrial septostomy is performed (percutaneous through the umbilical vein or femoral vein) to allow atrial-level mixing (Fig. 113.27). This procedure is usually effective in allowing sufficient atrial-level mixing so that the patient is adequately saturated (70%–80%).

After the procedure, the prostaglandin infusion can frequently be discontinued. In TGA-VSD, there is often sufficient shunting at the level of the VSD to promote adequate systemic saturation; in patients with large VSDs, the predominant presenting symptom may be pulmonary overcirculation and CHF. Patients with TGA with pulmonary atresia have ductal-dependent pulmonary blood flow. In patients with TGA-VSD and aortic arch hypoplasia or coarctation, PGE1 may be necessary to maintain ductal patency and systemic perfusion. Echocardiography is the primary diagnostic modality for TGA.

The treatment of TGA has evolved significantly during the years of surgical therapy for CHD. Initial success was achieved by surgical reconstruction to create a physiologic repair. The atrial switch operation involves a series of intraatrial baffles using a patch channel (Mustard procedure)[34] or infolding of the native

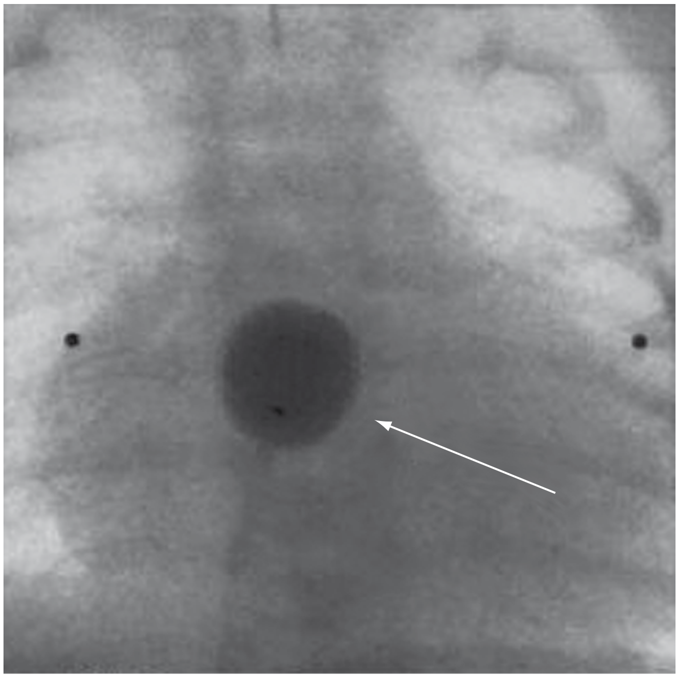

FIGURE 113.27 Angiogram during balloon atrial septostomy. The *arrow* points to the inflated balloon catheter at the atrial septum. The interventional cardiologist forcefully pulls the balloon across the patent foramen ovale to create an open, unobstructed secundum atrial septal defect.

atrial wall and interatrial septum (Senning procedure).[35] Both procedures achieve the same physiologic result: The systemic venous blood is redirected to the left ventricle (and the pulmonary circulation), and the pulmonary venous blood is redirected to the RV. After a successful atrial switch, patients are fully saturated but are left with their morphologic RV supporting the entire systemic cardiac output. In many (perhaps ultimately all) patients undergoing the atrial switch procedure, the RV becomes dysfunctional over time, which is manifested by dilation, decreased ejection fraction, tricuspid insufficiency, and dysrhythmias. The observation of problems with the systemic RV in patients after the atrial switch operation was the primary impetus behind the development and application of the arterial switch operation (ASO), which is now established as the surgical treatment of choice for patients with TGA. At the present time, operative survival rates for the ASO approach 100%.[36]

The ASO provides physiologic and anatomic correction of TGA by establishing ventriculoarterial concordance. The procedure involves transection and translocation of the malposed great vessels. The technically challenging requirement of the ASO relates to the translocation of the coronary arteries to the pulmonary root (the neoaorta). As noted, there are numerous possible branching patterns for the coronary arteries in TGA—some are easily transferred in the ASO, whereas others are more challenging (including single coronary ostium and intramural course) (Fig. 113.28).[37] Nonetheless, precise surgical techniques have been described and successfully applied to all coronary branching patterns. Given this as well as the known benefit of aligning the morphologic left ventricle with the systemic circulation, the ASO is offered to all patients with TGA regardless of the coronary branching pattern. There is no need for precise anatomic definition before surgery; all patients undergo the ASO. In most patients undergoing this procedure, the pulmonary artery bifurcation is moved anterior to the reconstructed neoaorta to minimize the potential for pulmonary artery distortion and compression of the translocated coronary arteries—the Lecompte maneuver (Fig. 113.29). Although there are interinstitutional biases in terms of nuances of treatment for TGA, the following surgical strategies are generally agreed on for this group of patients.

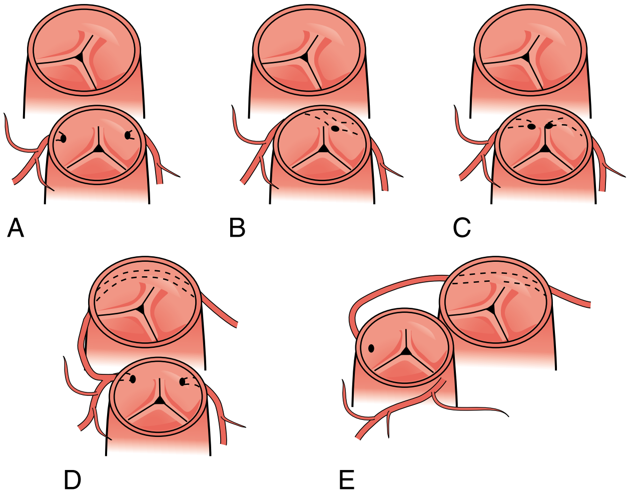

FIGURE 113.28 (A–E) Five basic coronary artery configurations, as described by Yacoub and Radley-Smith. (Adapted from Mee R. The arterial switch operation. In: Stark J, de Leval M, eds. *Surgery for Congenital Heart Defects.* 2nd ed. Philadelphia: Saunders; 1994:484.)

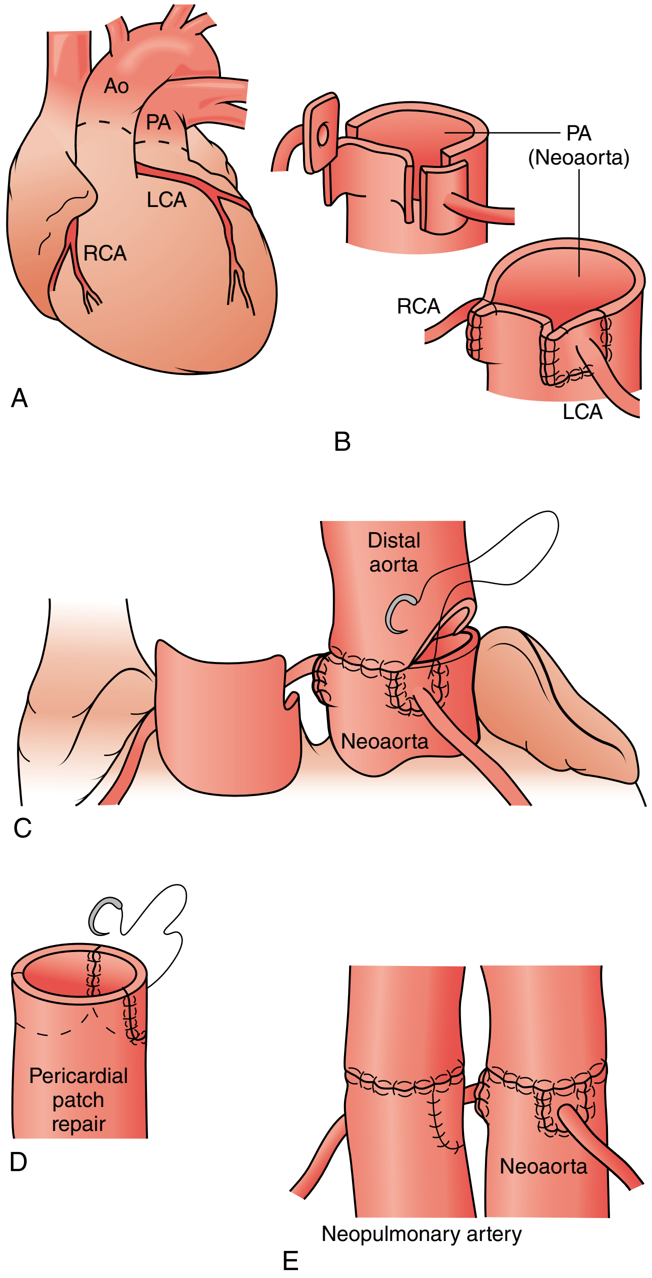

FIGURE 113.29 Arterial switch operation. (A) The aorta *(Ao)* and pulmonary artery *(PA)* are transected above the sinuses of Valsalva. (B) The coronary arteries are excised from the aorta and anastomosed to the pulmonary artery using a trapdoor technique. (C) The distal aorta is brought behind the pulmonary artery (Lecompte maneuver) and anastomosed to the neoaorta. (D) Separate pericardial patches are sutured to replace the excised coronary artery tissue from the aorta. (E) Completed repair. *LCA,* Left coronary artery; *RCA,* right coronary artery. (Adapted from Karl TR, Kirshbom PM. Transposition of the great arteries and the arterial switch operation. In: Nichols DG, Ungerleider RM, Spevak PJ, et al, eds. *Critical Heart Disease in Infants and Children.* Philadelphia: Mosby; 2006:721.)

Transposition of the great arteries–intact ventricular septum. After balloon atrial septostomy and weaning from PGE1, if possible, newborns with TGA-IVS undergo semielective ASO in the first few days to weeks of life. Rarely, patients present with profound desaturation refractory to balloon atrial septostomy and

PGE1; in this setting, an emergent ASO is indicated. We have found this to be necessary in one patient during the past decade in an experience involving more than 200 ASOs performed in newborns. For other patients, the ASO needs to be performed in a timely but nonemergent setting. Even in the presence of adequate systemic saturation, the patient's morphologic left ventricle is functioning in a low-pressure work environment—supporting the pulmonary circulation. Thus, left ventricle mass and function involute rapidly in the first few weeks of life. By 6 weeks of life, the left ventricle may be incapable of supporting the normal systemic workload after the ASO. As such, the preferred timing for the operation is in the first 1 to 2 weeks of life.

Transposition of the great arteries–ventricular septal defect with or without arch hypoplasia. There are several modes of presentation for patients with TGA-VSD. In patients with small, pressure-restrictive VSD, the presenting symptoms are similar to those of TGA-IVS. These patients require the ASO early in life, along with VSD closure before left ventricle involution. In patients with TGA and nonrestrictive VSD, there may be adequate mixing to allow reasonable systemic arterial saturation. In this setting, the left ventricle remains pressure loaded and does not involute; thus, the necessity of early promotion to the ASO is less time compressed. Many newborns with TGA and a large VSD are relatively asymptomatic soon after birth; they go on to develop CHF in the first 1 to 2 months of life as the normal decrease in newborn pulmonary resistance occurs. Our preference for these patients is to follow them closely for evidence of CHF and perform semielective ASO and VSD closure in the first 4 to 6 weeks of life. Some centers prefer to proceed with this surgery sooner; this appears to be a matter of surgeon preference and has not been shown to affect long-term outcome. In patients with TGA-VSD with arch hypoplasia or coarctation, early surgery is required. In this setting, the preferred treatment involves one-stage, complete correction, including ASO, VSD closure, and aortic arch repair.

Transposition of the great arteries–ventricular septal defect with pulmonary stenosis–left ventricular outflow tract obstruction or pulmonary atresia. The issue of concern in this group of patients is the degree of LVOTO. In patients with TGA-VSD and organic LVOTO, with a relatively normal pulmonary valve, the treatment strategy is as described earlier, with ASO, VSD closure, and left ventricular outflow tract (LVOT) resection. The situation becomes more complex in the setting of severe pulmonary stenosis or pulmonary atresia. These patients may be ductal dependent as newborns (pulmonary atresia) and require newborn complete correction or a palliative modified BT shunt in the newborn period, followed by biventricular repair later in infancy (our preference). The goal in these patients is to achieve biventricular repair to create an unobstructed connection between the morphologic left ventricle and systemic circulation. Several operations have been described and successfully used in this setting.

The Rastelli procedure involves an interventricular patch baffle, which commits the left ventricle to the aorta through the VSD. Typically, a RV–pulmonary artery conduit is then placed to achieve pulmonary blood flow. Issues of concern include the potential for LVOTO (at or below the level of the VSD) and the certain need for future RV–pulmonary artery conduit revision. The Réparation à l'Etage Ventriculair (REV) procedure is designed to minimize the potential of LVOT obstruction and to use all possible native tissue-tissue connections to limit the potential need for future surgery. This procedure involves resection of the muscular conus between the aorta and pulmonary roots, interventricular baffle of the left ventricle to the aorta, and translocation of the native main pulmonary artery to the RV (by a Lecompte maneuver) without the use of an intervening conduit. The final option involves aortic root translocation, which includes resection of the entire native aortic root and coronary origins, resection of the intervening muscular conus, and posterior translocation of the aortic root to the surgically enlarged pulmonary root to achieve a direct connection between the left ventricle and aorta. The VSD is then closed, and a conduit is placed, or a direct connection is created between the RV and pulmonary arteries.

Transposition of the great arteries in adults. The long-term prognosis of adult patients who have undergone childhood repair of TGA is still incompletely understood; however, all these patients require lifelong surveillance and have the potential to develop significant anatomic and functional cardiac problems. Patients who were treated with the atrial switch operation have a morphologic RV supporting their systemic circulation, which will predictably fail in many patients. Although fully saturated, these patients may present later in life with signs and symptoms of CHF and dysrhythmia. For severely affected individuals, the only realistic treatment option ultimately may be cardiac transplantation.

The long-term issues related to the ASO are less well understood. Despite technical advances in reconstructive methods, there is still a troubling incidence of postoperative supravalvular and branch pulmonic stenosis. The neoaortic root may dilate in some patients undergoing the ASO, leading to neoaortic insufficiency and coronary artery distortion. The fate of the surgically translocated coronary ostia is unclear; there is clearly a risk for late sudden cardiac death related to unsuspected coronary insufficiency noted elsewhere in this chapter. For an adult patient undergoing noncardiac surgery after previous surgery for complex congenital cardiac disease, including TGA, a high index of suspicion is warranted.

Double-Outlet Right Ventricle

Double-outlet RV occurs when both great vessels are anatomically committed to the RV. Double-outlet RV occurs in 3 to 9 per 100,000 live births. This condition may occur in association with a subaortic VSD, a noncommitted (remote) VSD, or a subpulmonary VSD (Taussig-Bing anomaly). As with other complex cardiac conditions, the goal of treatment relates to the presenting hemodynamic conditions and patient symptoms. The ultimate goal is to achieve a biventricular circulation when possible. Patients may present with severe cyanosis and require corrective or palliative therapy in the newborn period. Conversely, they may present with unrestricted pulmonary blood flow and develop CHF. The challenging issue of constructing a biventricular repair relates to achieving unobstructed outlets from the right and left ventricles. In patients with double-outlet RV with subaortic VSD and RVOTO, reconstruction is similar to that for TOF. More remote VSDs may require enlargement with interventricular tunnel repair. For the Taussig-Bing anomaly, the relationship of the VSD to the pulmonary artery makes the ASO the procedure of choice. These patients often have RVOTO and aortic arch hypoplasia, which require attention at the time of complete correction. For rare individuals, the relationship of the great vessels and complexity of the VSD preclude a biventricular repair, and the patient must be treated as if they have a functional single ventricle.

Congenitally Corrected Transposition of the Great Arteries (L-Transposition)

Congenitally corrected TGA (ccTGA, or L-TGA), describes a constellation of conditions with the common feature of A-V and ventriculoarterial discordance and occurs in approximately 1 in 33,000 live births. ccTGA may occur in association with VSD, pulmonic and subpulmonic stenosis, and displaced left A-V valve (Ebsteinoid left A-V valve). In ccTGA, the morphologic mitral valve is right-sided and associated with the morphologic left ventricle; the morphologic tricuspid valve is associated with the morphologic RV. Patients with this condition are physiologically corrected in that in the absence of ventricular-level shunting, they are fully saturated—hence, the term *corrected transposition.* The age and mode of patient presentation in this condition depend on the contribution of associated defects and the function of the morphologic RV, which acts as the systemic ventricle. Controversy exists regarding the timing and mode of surgical treatment for patients presenting with various manifestations of ccTGA.

Congenitally corrected transposition of the great arteries with intact ventricular septum. Patients with ccTGA-IVS may be entirely asymptomatic throughout childhood and early adulthood. Frequently, the diagnosis is made incidentally. In other patients, the disease manifests with symptoms of CHF in association with right ventricular dysfunction or left A-V valve insufficiency. There is also a high incidence of complete heart block in patients with ccTGA, and the first manifestation may be this dysrhythmia with associated symptoms.

Treatment for patients presenting with CHF is a challenging management scenario. For patients with ccTGA and preserved right ventricular function, left A-V valve repair or replacement may be considered. In many of these patients, the valvular insufficiency may be more a manifestation of declining systemic RV function, with septal shift and annular dilation, rather than intrinsic valve pathology. In this setting, valve replacement would not correct the progression of right ventricular dysfunction. For patients with systemic right ventricular dysfunction, one option for treatment is a complex reconstruction known as a *double switch* (Fig. 113.30). This procedure includes an atrial switch in combination with an arterial switch to align the morphologic left ventricle with the systemic circulation. In almost all patients with ccTGA-IVS and right ventricular dysfunction (and in the absence of structural LVOTO), a period of left ventricle retraining is required before the double-switch procedure. This requirement relates to the fact that the left ventricle will have been functioning in the low-pressure pulmonary circulation and will be incapable of performing systemic work. Retraining or conditioning the left

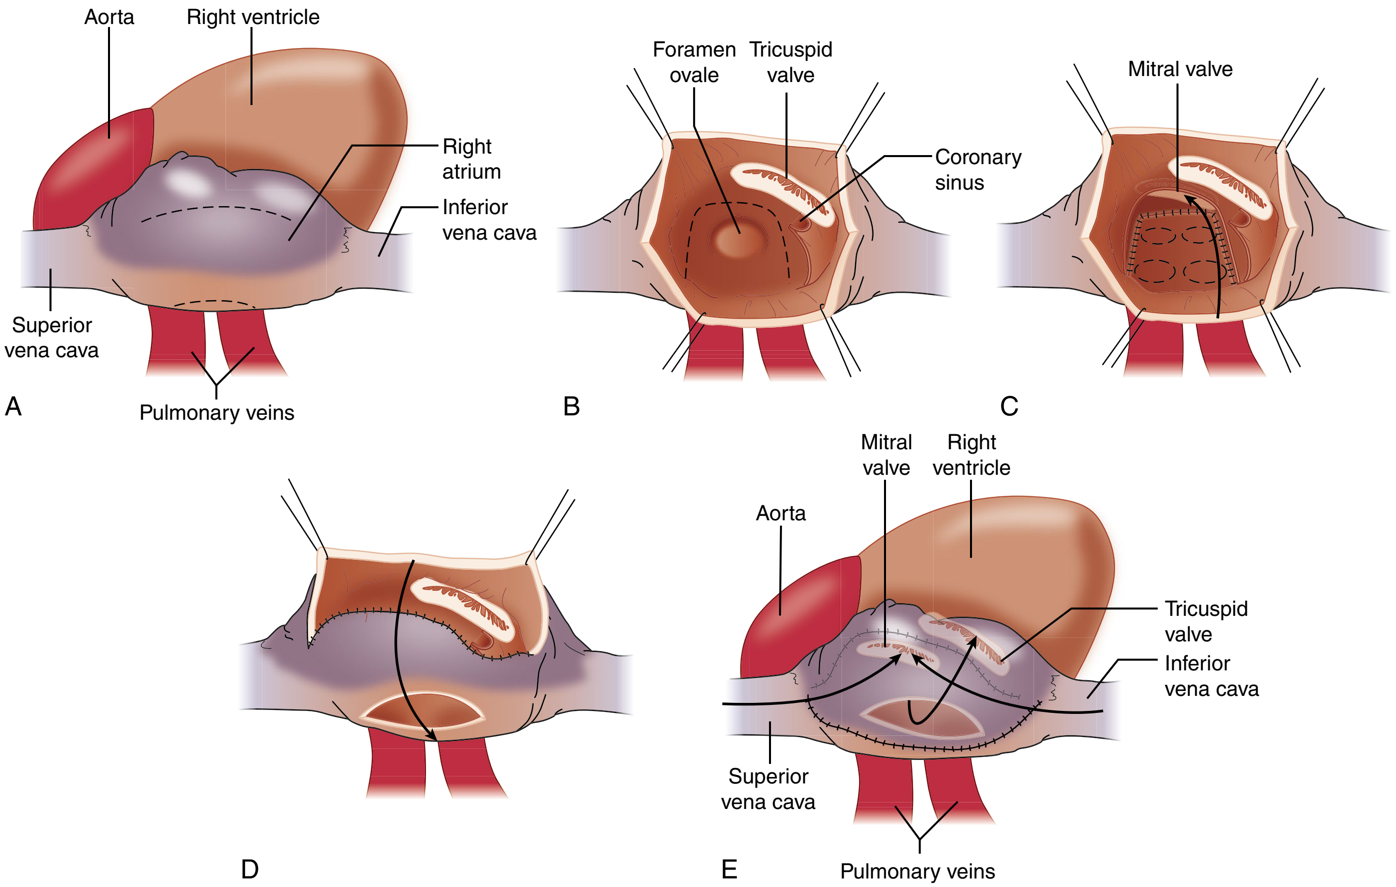

FIGURE 113.30 Schematic representation of the Senning procedure for transposition of the great arteries. (A) Two separate incisions, one in the right atrium and the other in the left atrium, near the insertion of the pulmonary veins. (B) Location of the incision in the atrial septum. (C) The atrial septum sewn down to the pulmonary veins, preparing for oxygenated blood to be directed to the tricuspid valve. The inferior free wall of the right atrium is sewn along the cut edge of the atrial septum, redirecting the deoxygenated blood to the mitral valve. (D) The superior free wall of the right atrium is now sewn to the cut edge of the left atrium, redirecting the oxygenated blood from the pulmonary veins to the tricuspid valve. (E) Schematic representation of the oxygenated blood and deoxygenated blood pathways. (Reprinted with permission from Texas Children's Hospital, 2016.)

ventricle requires the surgical creation of pulmonary stenosis by the placement of a pulmonary artery band. Most surgeons agree that the left ventricle must work at or very near systemic blood pressure for many months (we favor a minimum of 6 months) before the double-switch operation. The double switch is a technically challenging operation with significant perioperative risk. Because of the small numbers of patients treated worldwide with this complicated surgical strategy, there are only limited data on the acute and midterm results.[38] An issue of concern centers on the long-term ability of the retrained left ventricle to function as the systemic ventricle. Nonetheless, patients with ccTGA and depressed right ventricular function have a poor prognosis otherwise, and as such, the complexity and risk of the double-switch operation appear justified. The only other surgical option for these patients is cardiac transplantation.

Congenitally corrected transposition of the great arteries with ventricular septal defect and pulmonic stenosis. Patients in this category are often well balanced and have mild cyanosis, with minimal symptoms in childhood, whereas others with more severe pulmonary stenosis or pulmonary atresia present early in life with symptomatic cyanosis. Treatment for an overtly cyanotic infant with ccTGA with pulmonary stenosis is initially palliative in the form of a modified BT shunt. The ultimate goal for all patients is a biventricular circulation with normal arterial oxygen saturation. One option for these patients is to close the VSD surgically and place a conduit between the morphologic left ventricle and pulmonary arteries to relieve the pulmonary obstruction. This classic repair benefits the patient by separating the systemic and pulmonary circulations and allowing normal oxygen tension. The issue of concern in patients undergoing this repair is that the morphologic RV must act independently as the systemic ventricle after repair. As noted, the ability of the RV to support the systemic circulation may be questionable over the long term in some patients. As such, an alternative strategy in these patients is to baffle the left ventricular outflow to the aorta through the VSD, then to perform an atrial switch to reroute the systemic and pulmonary venous return, and finally to place a conduit from the morphologic RV to the pulmonary arteries. This option is a modification of the double-switch arrangement, affording the patient the benefit of a systemic left ventricle. Because the left ventricle has been working at systemic pressure before correction, a period of retraining is unnecessary.

Adult patients with ccTGA, with or without previous surgery, warrant careful attention before any noncardiac operation. These patients may have various complex ongoing cardiac issues, including rhythm disturbance, ventricular dysfunction, and valvular insufficiency.

Left Ventricular Outflow Tract Obstruction

LVOTO may manifest in isolation or in combination with other complex cardiac lesions. The physiologic consequences of severe LVOTO may be catastrophic, including diminished systemic cardiac output and tremendous left ventricular pressure overload. Newborns with severe LVOTO may present in shock with diminished peripheral perfusion, cardiomegaly, and pulmonary congestion. There is a significant risk of necrotizing enterocolitis in these infants. In older patients, gradual onset of LVOTO may be initially asymptomatic, only to manifest over time as decreasing exercise tolerance and declining left ventricular function. Patients with severe LVOTO and cardiomegaly are at high risk for myocardial ischemia and sudden cardiac death. The resting ECG often demonstrates left ventricular hypertrophy, with a strain pattern. If an exercise stress test is performed, it may demonstrate worrisome ST segment depression and ventricular dysrhythmias. Echocardiography is the primary diagnostic tool for patients with LVOTO. In rare cases, diagnostic cardiac catheterization may be considered to delineate the level of obstruction.

Valvular Aortic Stenosis

Congenital valvular aortic stenosis (AS) is a common cause of LVOTO and represents approximately 5% of all CHD. The degree of obstruction may range from mild in patients with a congenitally bicuspid aortic valve to severe in patients with critical AS with unidentifiable valve commissures and annular hypoplasia. Infants presenting with critical AS are often symptomatic early in the newborn period, presenting with shock and profoundly depressed ventricular function. At the present time, almost all patients are taken to the cardiac catheterization laboratory for balloon aortic valvotomy. This procedure may be lifesaving in relieving AS and allowing for recovery of ventricular function. However, for most patients, the procedure is palliative, with a significant incidence of recurrence of AS or development of significant aortic insufficiency after the procedure. In patients with AS refractory to balloon dilation, an open aortic valvotomy may be necessary (Fig. 113.31). A surgical valvotomy, especially in small infants with adequate annular dimension, can be accomplished by an accurate incision down a rudimentary commissure or raphe to improve cusp mobility.

Recurrent AS after previous ballooning may be amenable to repeat dilation; however, when associated with significant aortic insufficiency, the patient requires surgery. Severe aortic insufficiency after previous balloon dilation is usually related to an avulsed cusp. In these cases, valve repair may be possible, but replacement may become necessary. Published series have confirmed the usefulness of aortic valve repair procedures, which is a particularly attractive option for growing children.[39]

The decision to replace the aortic valve in growing children is clouded by the lack of an ideal aortic valve substitute—a valve

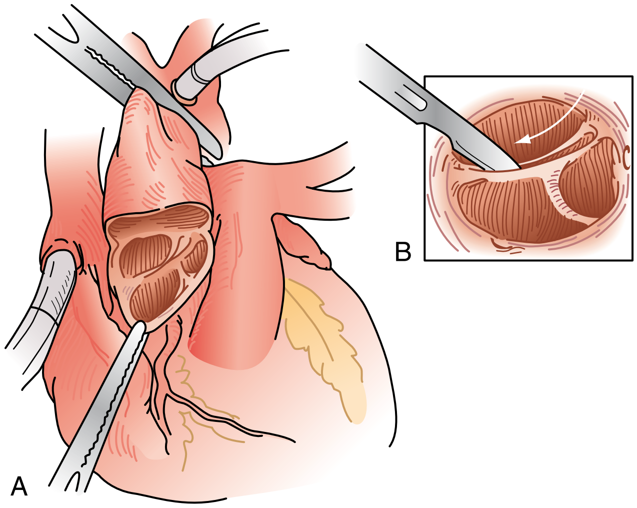

FIGURE 113.31 Close-up view of the aortic valve demonstrating a surgical valvectomy. (A) The valve is bicuspid, with a prominent raphe in the anterior valve leaflet. (B) The orifice is enlarged by incising the fused commissure between the two leaflets. (From Chang AC, Burke RP. Left ventricular outflow tract obstruction. In: Chang AC, Hanley FL, Wernovsky G, et al, eds. *Pediatric Cardiac Intensive Care*. Baltimore: Williams & Wilkins; 1998.)

capable of lifelong durability, appropriate somatic growth, easily implantable, and not requiring anticoagulation. Criteria for aortic valve replacement are beyond the scope of this chapter; however, severe valvular AS not amenable to catheter or open valvotomy is an appropriate indication. Options for aortic valve replacement in children include a mechanical prosthesis, heterograft, homograft, and pulmonary autograft. Additionally, the emerging option of partial heart transplant, as described earlier, is now a possible option. A mechanical prosthesis may be considered in childhood; however, the valve size must be sufficient to provide adequate function as the patient grows. Most surgeons and cardiologists recommend therapeutic anticoagulation in children with a mechanical valve prosthesis, but this can be challenging and potentially dangerous in growing children and adolescents. Many surgeons believe the risk for such medical treatment outweighs the potential benefit of a theoretically durable valve.

Heterograft aortic valve prostheses historically have been associated with limited durability in children and are not capable of somatic growth. A recent analysis in children has confirmed a significantly reduced long-term durability of heterografts compared with mechanical valves and the Ross operation.[40] Human cadaver aortic valves (aortic homograft) have been used extensively in children and young adults. These valves are usually implanted as a complete aortic root replacement, which requires coronary ostial implantation. Thus, surgery to place an aortic homograft is considerably more complex and with potentially higher risk. The positive features of an aortic homograft include improved durability compared with heterograft and avoidance of anticoagulation. Nonetheless, these valves eventually fail, necessitating a complicated reoperative aortic root replacement.

Pulmonary autograft aortic root replacement (Ross operation) involves translocation of the pulmonary valve to the aortic position with subsequent replacement of the pulmonary valve with a homograft or heterograft valved conduit (Fig. 113.32). The theoretical advantages of the Ross procedure include the potential for somatic growth, avoidance of anticoagulation, and possibility of extended durability. Enthusiasm for this procedure has been tempered by the recognition that the need for extensive cardiac dissection to harvest the autograft, along with a more complex implantation, is associated with increased operative risk. Furthermore, the unsupported pulmonary root may dilate in the presence of systemic arterial pressure, leading to progressive autograft aortic insufficiency. This observation has led to various modifications of the implantation technique to support the aortic annulus and the sinus segment. Given these considerations and the certain need for reoperation to replace the right ventricular–pulmonary artery conduit, great caution must be exercised in the application of the Ross operation.[41] Transcatheter aortic valve replacement has become a frequently used intervention for acquired aortic valve disease in adults. With the continued development of increasingly sophisticated and smaller means to perform transcatheter aortic valve replacement, this will likely become a potential treatment algorithm for congenital aortic disease in the near future.

Fibromuscular Subaortic Stenosis

Fibromuscular subaortic stenosis is a progressive narrowing of the LVOT related to a dense fibrous membrane usually found in association with asymmetric protrusion of the interventricular septum into the outflow tract. Fibromuscular subaortic stenosis accounts for approximately 6% of all CHD. The membrane is often concentric and becomes densely adherent to the septum and mitral valve. The membrane progresses toward and eventually onto the undersurface of the aortic valve cusps, which leads to progressive LVOTO, aortic valve cusp retraction, and aortic insufficiency.

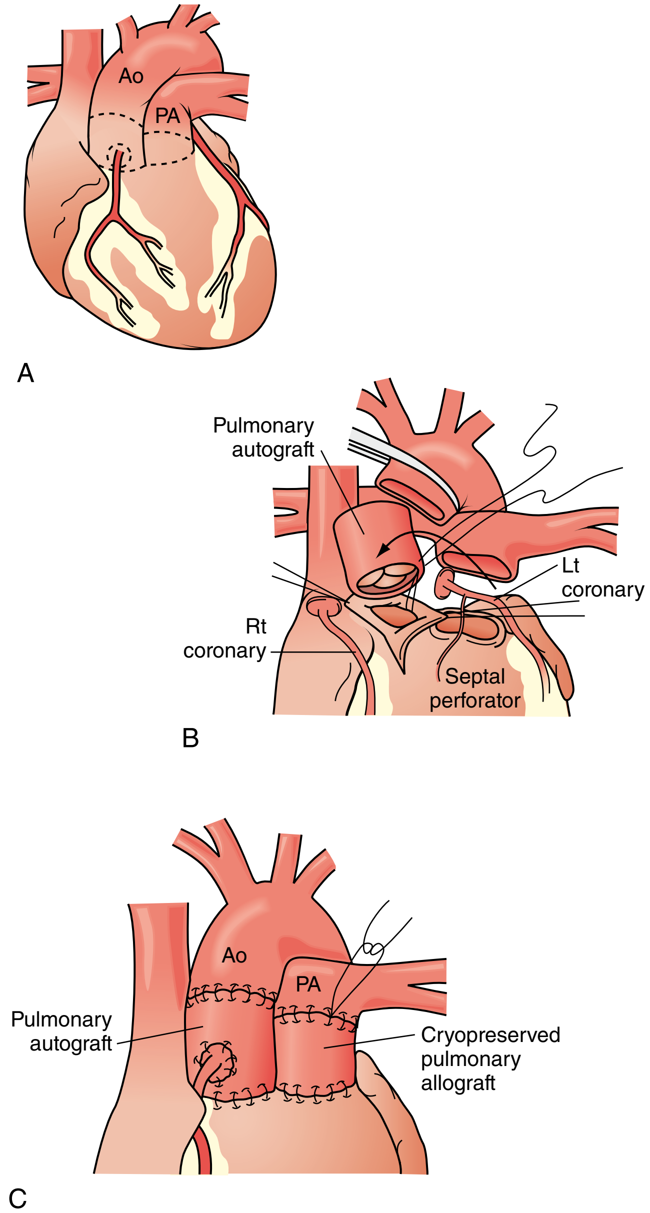

FIGURE 113.32 Ross procedure. (A) The great arteries are transected above the sinotubular ridge. The coronary arteries are excised using coronary artery buttons. (B) The pulmonary autograft is excised from the right *(Rt)* ventricular outflow tract, and the proximal end of the autograft is anastomosed to the annulus. (C) The coronary artery buttons are anastomosed to the pulmonary autograft. *Ao,* Aorta; *Lt,* left; *PA,* pulmonary artery. (Adapted from St Louis JD, Jaggers J. Left ventricular outflow tract obstruction. In: Nichols DG, Ungerleider RM, Spevak PJ, et al, eds. *Critical Heart Disease in Infants and Children.* Philadelphia: Mosby; 2006:615.)

Echocardiography is the primary diagnostic tool when assessing the degree of obstruction and progression of subaortic stenosis. However, it is not accurate for assessing subtle degrees of cusp extension.[42] Cardiac catheterization is rarely needed to diagnose this condition; balloon dilation is of no use in treating the LVOTO caused by this condition.

Surgery is the mainstay of treatment for subaortic stenosis, but there is disagreement about surgical indications. Most surgeons believe that new onset of any degree of aortic insufficiency in association with a subaortic membrane, regardless of the pressure gradient, is an indication for surgery. In other patients, an escalating LVOT gradient, associated left ventricular hypertrophy, and appropriate anatomic substrate are acceptable indications for operation.

The surgical procedure for subaortic stenosis involves a transaortic resection of the subaortic membrane, including all attachments to the mitral valve, septum, and aortic valve cusps. A septal myectomy is performed, along with membrane resection, in most patients (Fig. 113.33). Complications include membrane recurrence, injury to the bundle of His, and iatrogenic VSD creation. Nonetheless, with careful technique, the risk of these complications is minimized. Despite surgical intervention, a significant proportion of patients will have recurrence that requires reintervention, and upward of 40% will develop some degree of aortic insufficiency.[43]

Tunnel Subaortic Stenosis

Tunnel subaortic stenosis is a more severe form of LVOTO that is often associated with aortic annular hypoplasia and valvular AS. In severe cases, the LVOTO is not amenable to subaortic resection alone. In this situation, an aortic root–enlarging procedure may be necessary to relieve the obstruction (aortoventriculoplasty, or Konno procedure). This complex reconstruction is generally associated with the necessity of aortic valve replacement using one of the aforementioned options. Moreover, all degrees of LVOTO may be seen in association with numerous left heart obstructive lesions (Shone syndrome) that may require extensive reconstruction.

Aortic Arch Anomalies

Aortic Coarctation

Coarctation of the aorta is one of the most frequently encountered congenital cardiac lesions, occurring in 3 of every 10,000 live births. This condition has a wide range of presentations, from a severely symptomatic newborn with CHF and depressed ventricular function to an adult with proximal hypertension and minimal symptoms. Coarctation is classified relative to its association with the ligamentum arteriosus and aortic arch. An infantile or preductal aortic coarctation is seen in combination with a large PDA, which may have predominantly right-to-left flow to the lower descending aorta. In this setting, the patient is ductal dependent for systemic blood flow until the coarctation is repaired, and a PGE1 infusion must be maintained to prevent ductal closure. A periductal or juxtaductal coarctation occurs in the region of the ductal insertion and is distal to the aortic isthmus, which may be normal or hypoplastic (Fig. 113.34).

Aortic coarctation with or without aortic arch hypoplasia is frequently associated with intracardiac anomalies, including multiple left heart obstructive lesions (e.g., mitral stenosis, left ventricular hypoplasia or endocardial fibroelastosis, subaortic stenosis

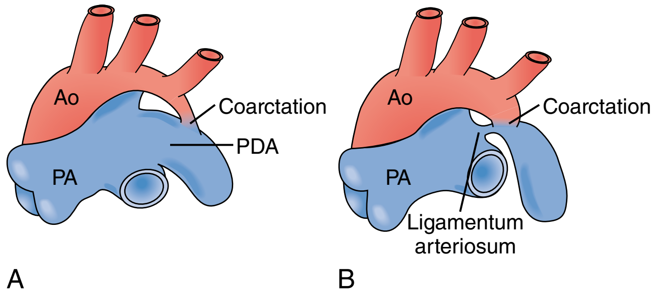

FIGURE 113.34 Coarctation of the aorta *(Ao).* (A) Infantile or preductal coarctation. (B) Adult coarctation. *PA,* Pulmonary artery; *PDA,* patent ductus arteriosus. (From Backer CL, Mavroudis C. or AS) known as *Shone syndrome.* Patients with large VSDs may present in infancy with severe aortic coarctation, with or without subaortic stenosis.

Aortic coarctation may be suspected on clinical examination by a significant upper extremity–lower extremity blood pressure gradient and diminished or absent femoral and pedal pulses. In older patients with well-developed intercostal collateral arteries, a continuous murmur may be auscultated over the posterior thorax. Echocardiography is now the primary diagnostic modality for aortic coarctation. MRI and CT angiography may also be useful in some patients. In rare cases, cardiac catheterization is required to define the anatomy, but this modality is now used more frequently for treatment, including balloon dilation with or without stenting.

Treatment strategies for aortic coarctation have evolved significantly since the first successful surgical treatment 80 years ago. Newborns presenting with severe aortic coarctation with or without associated ductal-dependent systemic blood flow are best treated by surgery. Initial enthusiasm regarding balloon dilation in these patients has diminished as it has become clear that there is a high incidence of recurrent coarctation after neonatal dilation.[44] Most congenital cardiac surgeons perform isolated coarctation repair through a left thoracotomy incision (third or fourth interspace) using resection of the coarctation and primary anastomosis. For patients with relative hypoplasia of the distal aortic arch, the anastomosis can be brought along the lesser curve of the aortic arch using an extended end-to-end method. For coarctation with a hypoplastic transverse arch, we favor the aortic arch advancement procedure, which uses all native tissue repair to allow for growth.[45] Other methods include subclavian artery flap aortoplasty (Waldhausen method) and prosthetic patch aortoplasty. These latter methods are used less frequently than primary repair (Fig. 113.35). Catheter therapy as a primary treatment for aortic coarctation is a controversial therapy in the opinion of most surgeons. Although this methodology has been widely applied, its true comparability to surgery requires further prospective study. There are several issues of concern regarding angioplasty for coarctation. The balloon dilation results in transmural disruption of the aortic wall in many patients, and there is an acute and ongoing risk for aneurysm formation. To limit this risk and minimize the potential of recurrence, off-label use of stents has been done for treatment of coarctation. Obvious issues of concern include somatic growth and lifetime risk potential of a metal device in the descending aorta.

Another controversial issue surrounds the concomitant treatment of coarctation and significant intracardiac pathology. Several series have demonstrated superior outcomes for simultaneous therapy in selected groups of patients, including neonates with large VSDs and coarctation with arch hypoplasia. Our approach to this condition has included one-stage complete repair of intracardiac defects, along with aortic arch advancement through median sternotomy on cardiopulmonary bypass.

In: Nichols DG, Ungerleider RM, Spevak PJ, et al, eds. *Critical Heart Disease in Infants and Children.* Philadelphia: Mosby; 2006:635.)

Interrupted Aortic Arch

IAA results from a lack of proper fusion and involution of the fetal aortic arches and represents 1.3% of all CHD. This is a fatal condition without treatment, and IAA is frequently associated with serious intracardiac pathology. IAA is classified based on the level of the interruption. Type A is distal to the left subclavian artery, type B occurs between left subclavian and left common carotid arteries, and type C occurs proximal to the left common carotid artery (Fig. 113.36). There is a frequent finding of an aberrant right subclavian artery (retroesophageal) from the descending aorta. Survival for patients with IAA is initially predicated on ductal patency; thus, a PGE1 infusion is required to stabilize the patient. Diagnosis is confirmed by echocardiography; other methods, including cardiac catheterization, are needed infrequently.

IAA requires surgical treatment in the newborn period, which typically involves simultaneous repair of intracardiac lesions (Fig. 113.37). Repair may be accomplished with the aid of an aortic arch augmentation patch, although a reported series

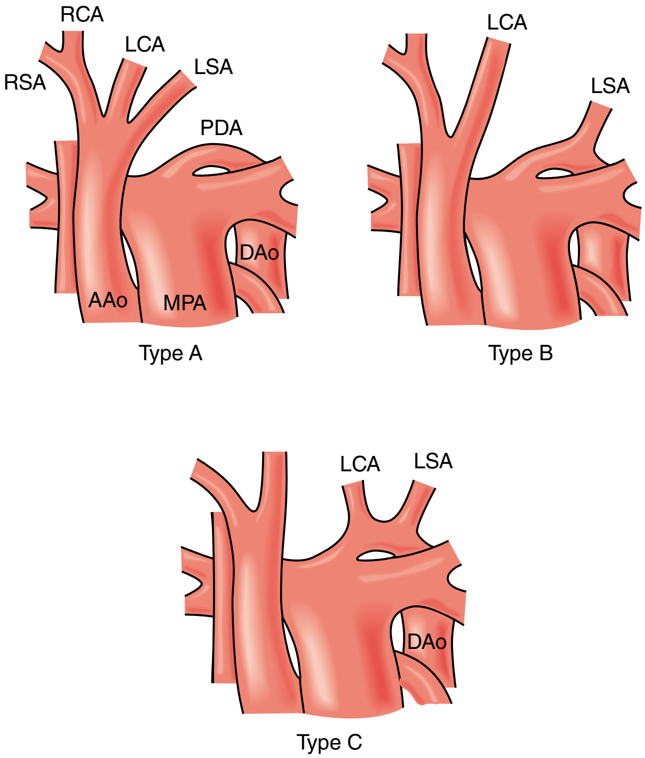

FIGURE 113.36 Classification of interrupted aortic arch. *AAo,* Ascending aorta; *DAo,* descending aorta; *LCA,* left common carotid artery; *LSA,* left subclavian artery; *MPA,* main pulmonary artery; *PDA,* patent ductus arteriosus; *RCA,* right common carotid artery; *RSA,* right subclavian artery. confirmed that a primary tissue-tissue repair can be performed in most patients and minimizes the potential for recurrent aortic arch obstruction.[46]

SINGLE VENTRICLE

Single-ventricle physiology is a frequently encountered form of CHD. Patients may present as newborns with inadequate pulmonary blood flow, excessive pulmonary blood flow, or balanced circulations. The single ventricle may be of right, left, or indeterminate morphology. Surgical treatment is required to provide adequate systemic oxygen delivery while protecting the pulmonary vasculature. The function of the single ventricle must be preserved to afford the patient the best possible long-term outcome.

The rapid evolution of successful palliation for patients with various forms of single-ventricle physiology since the late 1970s has led to a large and growing population of adults with a single ventricle. For most of these patients, lifelong cardiac attention is needed, and the potential for subsequent cardiac reoperation is high. Patients in this category who present for noncardiac surgery may be especially difficult to manage because of their challenging physiology.

An exhaustive discussion of the various forms of single ventricles is well beyond the scope of this chapter. This discussion is limited to common forms of single right and left ventricles to provide examples of the surgical management strategies for a single ventricle.

Tricuspid Atresia

Tricuspid atresia is the template of a single-ventricle lesion for which most current palliative strategies were developed. Tricuspid atresia occurs in 1 of every 10,000 live births. Patients with tricuspid atresia have a single morphologic left ventricle and may have normally related or transposed great vessels (Fig. 113.38). They may present with excessive pulmonary blood flow and require pulmonary artery banding early in infancy to relieve pulmonary overcirculation and CHF. Conversely, patients may have pulmonary stenosis or pulmonary atresia and require creation of a modified BTT shunt to provide adequate pulmonary blood flow and systemic oxygenation.

As noted, the initial palliative goals in patients with tricuspid atresia include adequate systemic oxygenation, protection of ventricular function, and adequate pulmonary arterial growth. Patients with ductal-dependent pulmonary blood flow require an mBTT shunt in the newborn period. We prefer to construct the shunt to the morphologic right pulmonary artery through a right thoracotomy. This construction allows shunt flow to be governed by the size of the right subclavian artery. Furthermore, the right pulmonary artery is typically longer and runs in a more horizontal plane compared with the left pulmonary artery; this facilitates avoiding distortion of a lobar branch. The goal of the shunt is to protect the pulmonary arteries, promote adequate pulmonary artery development, and support systemic arterial oxygenation for the first 4 to 6 months of life until the next planned stage of palliation (see later discussion of Glenn and Fontan operations). The shunt is not designed for long-term use; thus, in most patients, a small interposition graft (expanded polytetrafluoroethylene, 3.0–4.0 mm) is selected. In the early era of single-ventricle palliation, less well-controlled shunts were constructed, including classic Blalock (divided native subclavian artery to branch pulmonary artery), Pott's (side-to-side left pulmonary artery to descending aorta), and Waterston (side-to-side right pulmonary artery to ascending aorta) shunts (Fig. 113.39). These native tissue-tissue connections are capable of somatic growth but have the confounding risks for pulmonary overcirculation, pulmonary artery hypertension (potentially irreversible), and branch pulmonary artery distortion with hypoplasia. During the early stages of development of single-ventricle palliation, many patients were treated with these poorly controlled shunts. Thus, significant numbers of adult patients present with complications of these palliations, including chronic cardiac volume overload and decreased ventricular function, severe pulmonary artery distortion or isolation, pulmonary vascular disease, and profound cyanosis. These patients may present for surgery for noncardiac illness and are extremely difficult to manage.

Hypoplastic Left Heart Syndrome

Hypoplastic left heart syndrome (HLHS) is the prototypical single RV. HLHS occurs in 8 to 25 per 100,000 live births. Patients with this condition present with inadequate left heart structures ranging from mitral stenosis and AS with left ventricular hypoplasia to almost complete absence of the left heart structures with aortic and mitral atresia. In the case of aortic and mitral atresia, the ascending aorta is typically small (1–2 mm) and is perfused through retrograde aortic arch flow provided by the PDA. In HLHS, ductal closure results in rapid cardiovascular collapse, with profound systemic hypoperfusion and hypoxia, followed quickly by death. Therefore, in cases of prenatal diagnosis, patients must be born in a facility qualified to institute appropriate medical management immediately, including the establishment of

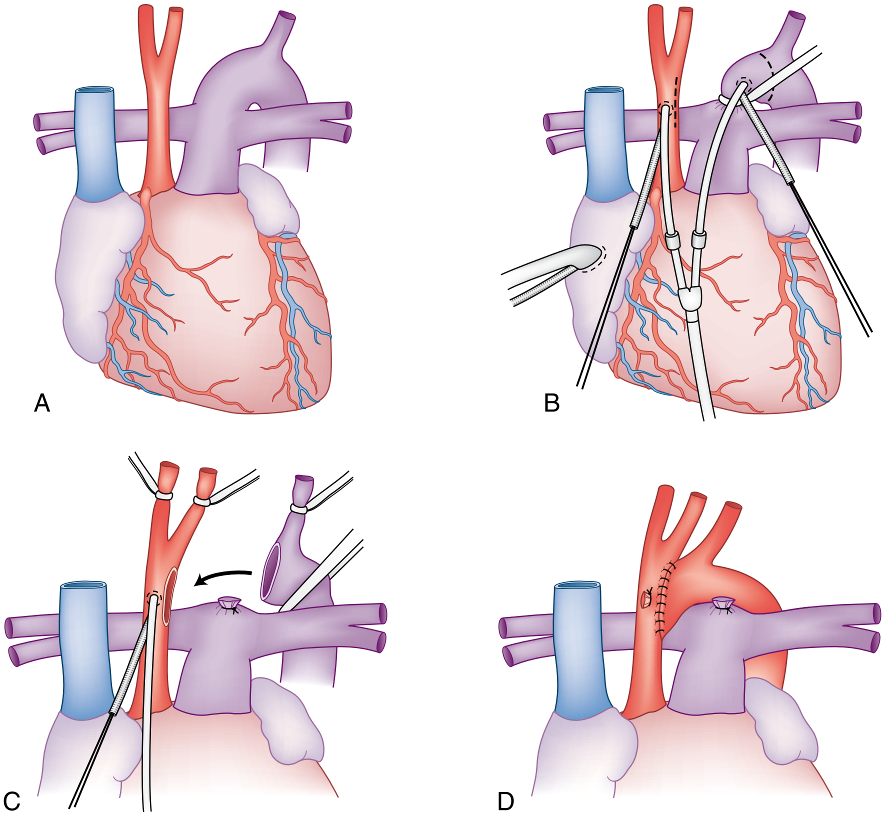

FIGURE 113.37 (A) Type B interrupted aortic arch. (B) Cannulation and site of incision for repair. The descending thoracic aorta is brought upward into the mediastinum (C) and then anastomosed to the ascending aorta in an end-to-side fashion (D). (From Hirooka K, Fraser CD. One-stage neonatal repair of complex aortic arch obstruction or interruption. *Tex Heart Inst J.* 1997;24:317-321.)

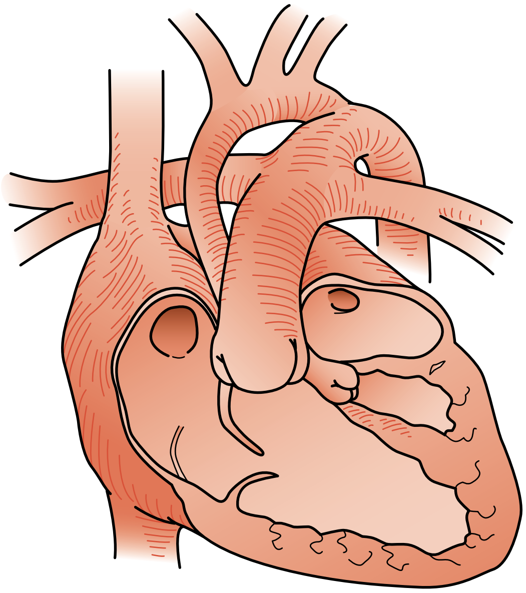

FIGURE 113.40 Anatomy of hypoplastic left heart syndrome. The tiny ascending aorta is seen arising from a markedly hypoplastic left ventricle. The ductus arteriosus is large, providing forward flow to the systemic circuit. The right ventricle is hypertrophied, and the pulmonary artery is enlarged. (From Wernovsky G, Bove EL. Single ventricle lesions. In: Chang AC, Hanley FL, Wernovsky G, et al, eds. *Pediatric Cardiac Intensive Care.* Baltimore: Williams & Wilkins; 1998.)

suitable vascular access (umbilical artery catheter) and institution of intravenous PGE1 to maintain ductal patency. Patients with HLHS undiagnosed at birth typically have an early grace period of a few hours, but with the initiation of ductal closure, these children become critically ill and require aggressive resuscitation for survival. Although most children with HLHS are otherwise normal, without treatment, HLHS is a uniformly fatal condition (Fig. 113.40).

After delivery, medical treatment is directed at maintaining ductal patency and balancing systemic and pulmonary blood flow. Balancing the circulations becomes increasingly challenging with the normal decline in neonatal PVR, resulting in massive pulmonary overcirculation. As the overcirculation progresses, infants become tachypneic and may exhibit decreased systemic perfusion. Necrotizing enterocolitis is a significant risk in these children, and if there is any question of visceral malperfusion, many centers avoid enteral nutrition in an effort to minimize this potential. Other medical maneuvers include deliberate hypoventilation, low inspired oxygen concentration, and additional carbon dioxide in an attempt to increase PVR and limit pulmonary flow. These options are of limited use in newborns with HLHS; over days to weeks, the infants become progressively ill with pulmonary congestion and marginal systemic cardiac output. Patients who are maintained have the potential of developing increased PVR as they age, and there is a known association between advanced age (>30 days) and increased operative mortality.

Surgery in the newborn period is the only realistic option for long-term survival in infants born with HLHS. Outcomes for surgical palliation of HLHS have come to be synonymous with the reputation of the treating center and surgeons. As with tricuspid atresia, patients with HLHS require a staged palliative approach. In the experiences of all centers, the first stage is the most challenging and risk laden. The various first-stage options are described in the following sections.

Neonatal Cardiac Transplantation

Transplantation is a theoretically attractive option in infants with HLHS that replaces the malformed heart with a structurally normal one. Leonard Bailey was an influential champion of this approach and was the first to report exciting results with transplantation in newborns with HLHS.[47] Furthermore, although there is an ever-present risk for rejection and infection in children with heart transplants, long-term meaningful survival is possible, and the quality of life of the recipients is good. The option of cardiac transplantation is limited by the small number of suitable donor hearts, and most children with HLHS are unable to survive the wait time for a donor graft. This situation has led most centers to abandon cardiac transplantation as the primary mode of therapy for most neonates with HLHS.

Norwood Reconstruction

After initial work and success at Boston Children's Hospital, Norwood and colleagues[48] gained international attention at the Children's Hospital of Philadelphia for developing and implementing a reconstructive technique to palliate newborns with HLHS; this methodology now carries the widely used eponym of the *Norwood procedure.* This procedure was gradually refined as experience accrued. The most common method involves surgical connection of the divided main pulmonary artery to the reconstructed aortic arch. In almost all children with HLHS, there is associated aortic arch hypoplasia with coarctation. A critical feature of the operation is to reconstruct the aortic arch to provide unrestricted systemic blood flow. Most surgeons use some form of prosthetic material, usually pulmonary artery homograft patching. Some surgeons have reported accomplishing the arch reconstruction without the necessity of additional material. After reconstructing the aortic arch, the divided main pulmonary artery is anastomosed to the arch and small ascending aorta to create a neoaortic confluence providing systemic output from the RV. The challenging feature of the reconstruction involves the accurate connection of this often-miniscule ascending aorta to the confluence of the arch and main pulmonary artery stump. The risk for torsion and coronary insufficiency is high. The final element of the classic Norwood reconstruction is the creation of a controlled source of pulmonary blood flow in the form of a modified BTT shunt (Fig. 113.41).

Sano Modification of the Norwood Operation

Achieving survival after the Norwood operation is challenging, involving innumerable technical and medical details. At best, after a Norwood procedure, the patient is fragile, with a delicate balance between systemic and pulmonary blood flow. This fact and the observation of widely disparate outcomes for the procedure have led to many important advances in the treatment of these children. One issue relates to the difficulty of balancing the systemic-to-pulmonary artery shunt, which lowers diastolic blood pressure (and coronary perfusion pressure) and volume loads the heart. Sano and associates[49] from Okayama University in Japan were the first to report a series of infants undergoing a successful Norwood procedure with the modification of a RV–pulmonary artery conduit rather than a modified BTT shunt. The theoretical advantage of this approach is the increase in diastolic pressure, creating a physiology more similar to a banded circulation rather than shunted circulation. Early reports with this method were encouraging, although patients appeared to become more rapidly desaturated as they aged compared with the shunted patients. The long-term effects of the right ventriculotomy on cardiac function are unknown. In one report, patients undergoing the Norwood operation were randomly assigned to receive an RV–pulmonary artery shunt or a modified BTT shunt. Transplantation-free survival was higher 12 months after randomization in the RV–pulmonary artery shunt group, as was the rate of unplanned reinterventions and complications.[50] More recent updates on the same cohort revealed no difference in transplant-free survival at 6 years after randomization between the RV–pulmonary artery shunt group and the modified BTT shunt group. However, the RV–pulmonary artery group did have a greater number of catheter-based interventions.[51]

Hybrid Procedure

The notion of a combined therapy between interventional cardiology and surgery for the first-stage palliation of HLHS has achieved significant attention. The idea is to minimize the risk of the first operation by banding the branch pulmonary arteries and delivering a stent into the ductus arteriosus to maintain patency. This hybrid arrangement is designed to allow newborn survival so

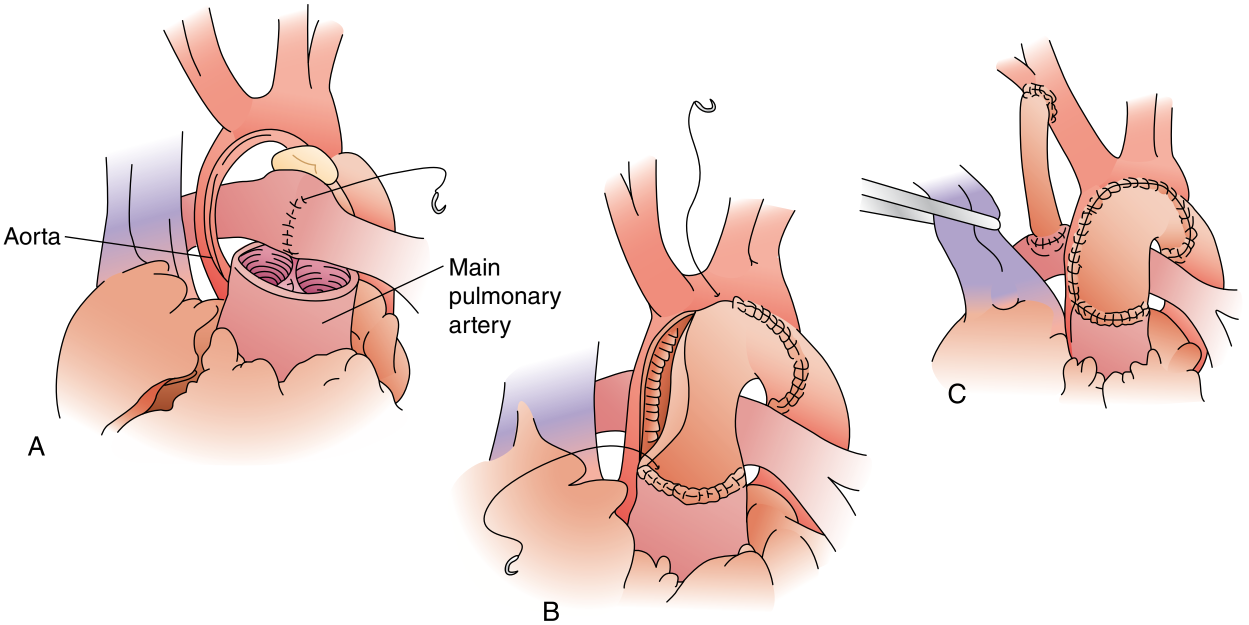

FIGURE 113.41 Norwood procedure for first-stage palliation of hypoplastic left heart syndrome. (A) The main pulmonary artery is divided proximal to the bifurcation, the ductus arteriosus is ligated and divided, and the aortic arch is opened from the level of the transected main pulmonary artery to a point distal to the ductal insertion in the descending aorta. (B) A segment of homograft is cut to an appropriate size and shape. This is sutured into place, creating an unobstructed outflow from the right ventricle to the pulmonary artery and aorta. (C) Polytetrafluoroethylene tube graft is placed from the innominate artery to the right pulmonary artery. The atrial septectomy is done while the patient is under circulatory arrest. (From Castaneda AR, Jonas RA, Mayer JE, et al. Hypoplastic left heart syndrome. In: *Cardiac Surgery of the Neonate and Infant.* Philadelphia: Saunders; 1994.)

that a more complete reconstruction may be performed later in infancy in a larger child. There appears to be a significant learning curve with this approach, as with any new procedure, and the incidence of complications warrants further study. Data have shown that the prevalence of necrotizing enterocolitis after the hybrid procedure is significant and comparable to reports after the Norwood procedure.[52] A recent meta-analysis revealed increased early mortality and worse 1-year transplant-free survival in patients undergoing the hybrid procedure compared with the Norwood. However, it is noted that the hybrid procedure was preferentially used in higher-risk patients, thus making it difficult to draw firm conclusions.[53] In addition, concerning features include the effect of the banding on long-term pulmonary artery growth, the fact that cardiac perfusion is still retrograde through the aortic arch, and the risk profile of the more extensive reconstruction later in life. The true place for this mode of therapy is unclear at the present time, but it represents an important direction of advancement to optimize the opportunity for survival of these children.

Fontan Operation

The long-term goal of single-ventricle palliation is to optimize ventricular function and promote systemic oxygen delivery. As noted earlier, patients with a single ventricle who are shunted or banded have ongoing concerns, including systemic desaturation, continued intracardiac mixing, and chronic cardiac volume overload. The current strategy for addressing these concerns uses a direct connection between the branch pulmonary arteries and systemic venous return, as initially proposed by Fontan in the early 1970s. The Fontan operation is now the treatment of choice for children born with all varieties of single ventricle and provides acceptable long-term palliation in suitable patients. However, the Fontan circulation is not normal and, even in the best of circumstances, results in significant alteration in normal cardiorespiratory physiology.

The Fontan circulation is established by connecting the systemic venous return directly into isolated branch pulmonary arteries without an intervening power source. Thus, blood flow in the Fontan circuit is passive, being promoted only by the pressure differential between the systemic venous system and pulmonary venous atrium. An impediment to flow in the systemic-to-pulmonary pathway results in a poor Fontan outcome. Established criteria for creating an effective Fontan circulation include the ability to connect the systemic venous return surgically to the pulmonary arteries in an unobstructed manner, normal pulmonary artery architecture and resistance, normal pulmonary venous drainage and low left atrial pressure, absence of significant A-V valve regurgitation, good ventricular function (and low ventricular end-diastolic pressure), an unobstructed systemic arterial outlet, and good systemic semilunar valve function. Compromise of any of these elements may compromise the quality of the Fontan circulation.

The Fontan operation has undergone several technical modifications in the 50 years of successful application to patients with single-ventricle physiology. Many patients underwent an atriopulmonary connection in which the open right atrial appendage was directly anastomosed to the pulmonary artery bifurcation with surgical closure of the ASD. Many of these patients present as adults with extreme dilation of the right atrium, with resulting sluggish flow to the pulmonary arteries, hepatic congestion, and atrial dysrhythmias (Fig. 113.42). Today, the most widely practiced modification of the Fontan operation is the total cavopulmonary connection. First described by DeLeval, this operation involves connection of the divided SVC to the superior and inferior aspects of the right pulmonary artery (typically offset), along with the creation of a channel to direct the IVC flow into the pulmonary arteries. The channel may be created using a surgically created lateral tunnel in the right atrium (Fig. 113.43) or interposing a conduit between the IVC and pulmonary arteries (extracardiac Fontan) (Fig. 113.44).

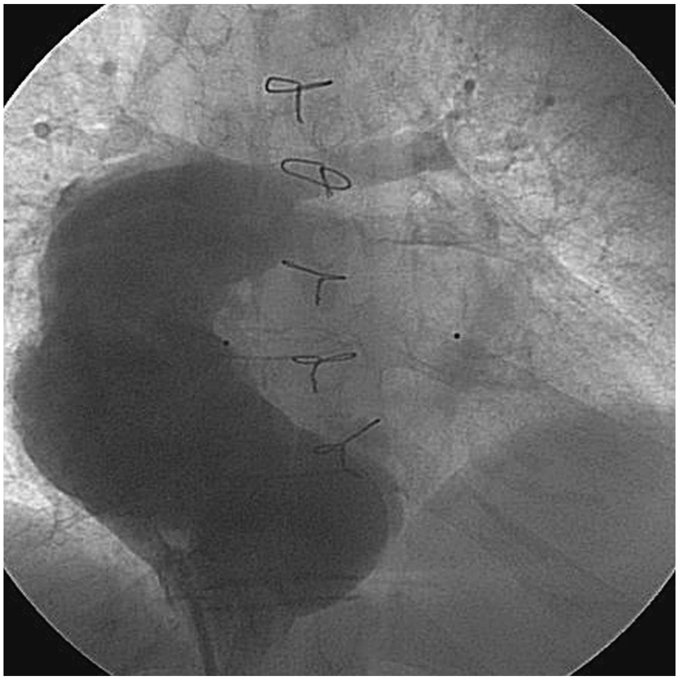

FIGURE 113.42 Angiogram of a dilated right atrium in a patient with an atriopulmonary Fontan connection.

The change from a volume-loaded circulation in patients with a single ventricle who are shunted or banded to a Fontan circulation results in acute volume unloading of the systemic ventricle. In the chronically overloaded heart, this acute change may be poorly tolerated, with resultant diastolic dysfunction and decreased ventricular compliance. To deal with this problem, patients with a single ventricle typically undergo an intervening stage of palliation in the form of a bidirectional, superior cavopulmonary anastomosis (Glenn shunt). The bidirectional Glenn shunt is constructed by anastomosing the cephalad end of the divided SVC to the superior aspect of the right pulmonary artery (Fig. 113.45). Other sources of pulmonary blood flow are typically eliminated, and the heart is volume-unloaded; however, systemic cardiac output is maintained because the IVC return is preserved. After the Glenn shunt, the patients are not fully saturated; typically, patients have saturations of approximately 80%. Over time, the unloaded ventricle remodels, and the patient is promoted to reoperation and completion of the Fontan circulation.

Perioperative care of a patient after a Fontan procedure can be challenging. The acute changes in cardiac volume loading may negatively affect cardiac output. Even in patients with supposedly ideal Fontan connections, the central venous pressure acutely increases to 12 to 15 mm Hg. Consequences of this increased venous pressure include pleural effusions, hepatic congestion, and ascites. In marginal Fontan candidates, some surgeons routinely place an intentional leak, or fenestration; the goal here is to preserve

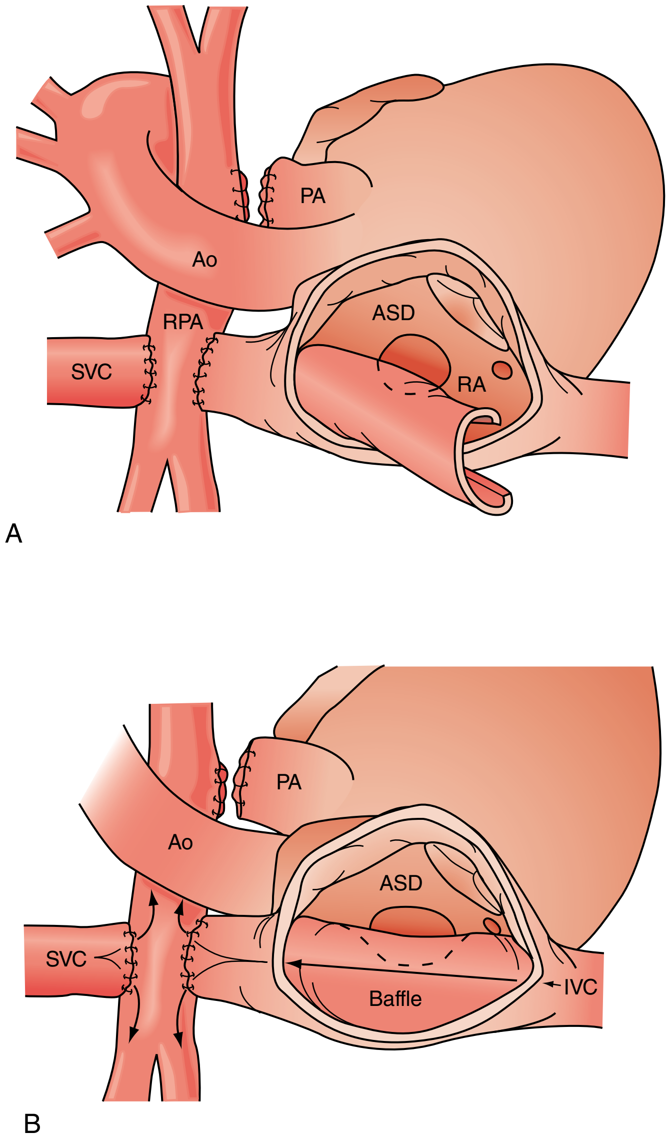

FIGURE 113.43 (A–B) Lateral tunnel Fontan procedure. *Ao,* Aorta; *ASD,* atrial septal defect; *IVC, i*nferior vena cava; *PA,* pulmonary artery; *RA,* right atrium; *RPA,* right pulmonary artery; *SVC,* superior vena cava. systemic ventricular volume loading and decrease systemic venous congestion at the expense of some degree of desaturation caused by the right-to-left shunting. The practice of routine fenestration after the Fontan operation has been examined, and some early data have shown that excellent outcomes can be achieved with highly selective application of a fenestration, which mitigates the risks associated with such a procedure, including hypoxia and systemic embolism.[54] Any impediment to passive pulmonary blood flow will inhibit Fontan flow and result in heart failure. Positive pressure ventilation, especially elevated levels of positive end-expiratory pressure, impedes pulmonary blood flow in the Fontan patient. Conversely, early extubation and effective spontaneous ventilation will improve pulmonary blood flow in the Fontan patient. Data have suggested that early extubation in the operating room for patients after the Fontan procedure improves hemodynamics, decreases the length of stay for patients, and decreases hospital costs.

The chronic complications of living with a Fontan circulation are still unfolding and include chronic hepatic congestion and cirrhosis, protein-losing enteropathy, atrial dysrhythmias, and venous stasis disease. Management of patients with failing Fontan circulations is especially challenging. These patients are at high risk for severe cardiac compromise while undergoing general anesthesia with positive pressure ventilation or any procedure involving large fluid shifts, including abdominal surgery. Patients with chronic hepatic congestion may develop a coagulopathy related to a decrease in factor production.

MISCELLANEOUS ANOMALIES

Vascular Rings and Pulmonary Artery Slings

Vascular Rings

Vascular rings are abnormalities of the aortic arch and its branches, compressing the trachea, esophagus, or both. The ring may be complete or partial. Categorization of the defects is useful for description:

Complete vascular rings
- Double arch: Equal arches or left or right arch dominant (Fig. 113.46)
- Right arch: Left ligamentum arteriosus from anomalous left subclavian artery
- Right arch: Mirror image branching, with left ligamentum from descending aorta

Partial vascular rings
- Left arch: Aberrant right subclavian artery
- Left arch: Innominate artery compression

The double aortic arch is the most common form of complete ring. Two arches arise from the ascending aorta, forming a true ring. The left arch is usually smaller. The right arch–left ligamentum complex is formed from persistence of the right fourth arch and regression of the left fourth arch. The anomalously arising left subclavian artery is often associated with a diverticulum at its base (Kommerell diverticulum). In partial rings, the most common form is an aberrant right subclavian artery arising distal to the left subclavian artery with a left arch. The right subclavian artery passes behind the esophagus from left to right. Innominate artery compression arises from a more posterior and leftward origin of the innominate artery from a left arch, leading to anterior compression of the trachea.

Pulmonary Artery Slings

A pulmonary artery sling occurs when the left pulmonary artery arises from the right pulmonary artery, passing leftward between the trachea and the esophagus. The ligamentum arteriosum attachment from the main pulmonary artery to the undersurface of the aorta forms a vascular ring around the trachea but not the esophagus. The trachea may be compressed, the cartilage may be soft, or there may be intrinsic stenosis of the trachea in the form of complete cartilage rings.

Diagnosis and Indications for Intervention

Symptoms reflect the degree of tracheal and esophageal compression from complete rings as well as the presence of coexistent tracheomalacia or stenosis. Upper respiratory symptoms predominate, with a characteristic brassy cough, recurrent respiratory infections, failure to thrive, and sometimes esophageal motility problems. In children, documentation of a ring is an indication for surgery. Older patients are often asymptomatic. Initially, the diagnosis is based on a high index of suspicion, and barium swallow is the first investigation. Echocardiography can document an abnormal head and neck vessel branching pattern, excluding intracardiac abnormalities. MRI provides complete anatomic detail.

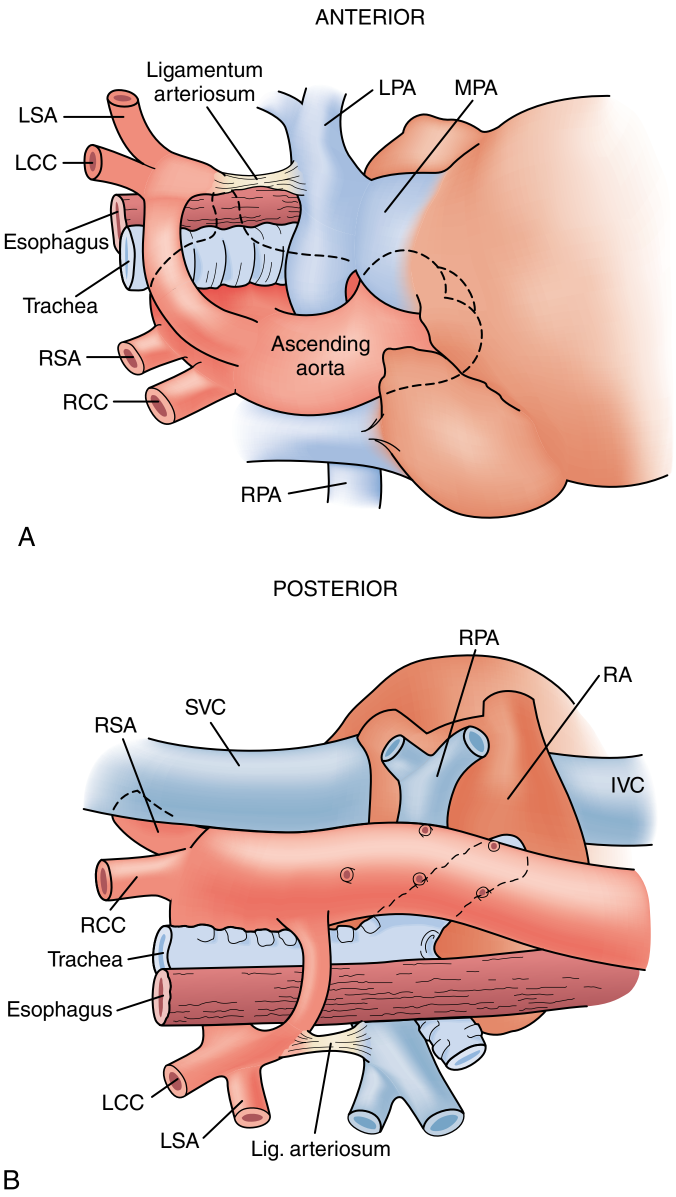

FIGURE 113.46 Double aortic arch, anterior (A) and posterior (B) views. *IVC,* Inferior vena cava; *LCC,* left common carotid artery; *Lig.,* ligamentum; *LPA,* left pulmonary artery; *LSA,* left subclavian artery; *MPA,* main pulmonary artery; *RA,* right atrium; *RCC,* right common carotid artery; *RPA,* right pulmonary artery; *RSA,* right subclavian artery; *SVC,* superior vena cava. (Adapted from Jonas RA. *Comprehensive Surgical Management of Congenital Heart Disease.* New York: Hodder Arnold; 2004:499.)

Surgery

Most vascular rings are accessible through a left posterolateral thoracotomy; the exception is a left arch with right-sided ligamentum. Division of the ring and, in the case of double arch, preservation of the dominant arch is performed. Preservation of the recurrent laryngeal nerve is important. Initial experience with endoscopic robotically assisted repair of vascular rings has also been reported.

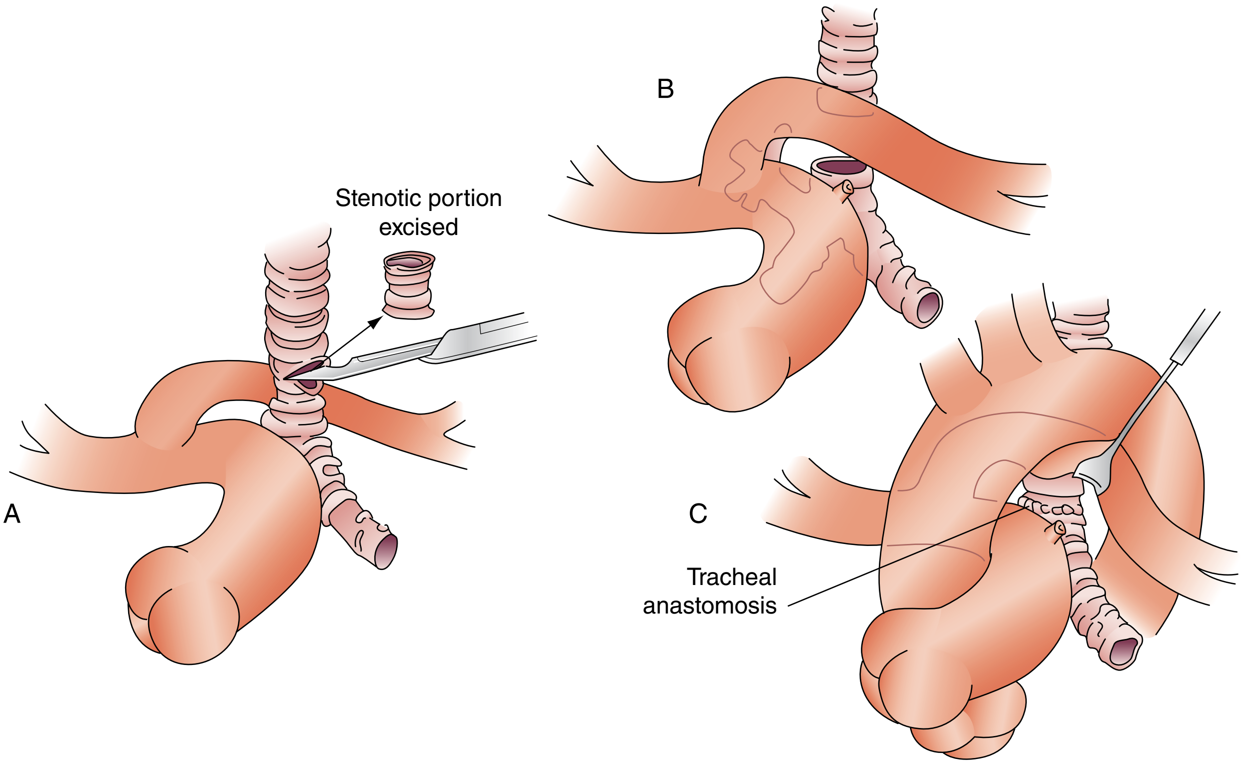

FIGURE 113.47 Method for the management of a pulmonary artery sling with associated tracheal stenosis, using cardiopulmonary bypass. (A) Tracheal resection of the involved segment. (B) Anterior translocation of the left pulmonary artery after transection of the trachea. (C) Direct anastomosis of the trachea. (From Castaneda AR, Jonas RA, Mayer JE, et al. Vascular rings, slings, and tracheal anomalies. In: *Cardiac Surgery of the Neonate and Infant*. Philadelphia: Saunders; 1994.)

Pulmonary artery slings are approached through the midline; the use of cardiopulmonary bypass facilitates tracheal reconstruction and relocation of the right pulmonary artery (Fig. 113.47). Repair can be achieved with low risk. Symptoms may take months to resolve, with slow resolution of the underlying tracheomalacia.

Coronary Artery Anomalies

Anomalies occur as a result of anomalous origin, termination, courses, and aneurysm formation. Of these variables, only an anomalous left coronary artery rising from the pulmonary artery (ALCAPA) and coronary artery fistulas are discussed here.

Anomalous Left Coronary Artery Rising From the Pulmonary Artery

An ALCAPA is a rare, often lethal lesion in early infancy. Untreated, the mortality rate approaches 90%.

Anatomy and pathophysiology. Developmentally, failure of the normal connection of the left coronary artery bud to the aorta results in an abnormal connection to the pulmonary artery. The abnormal origin can be situated in the main pulmonary artery or proximal branches. Associated abnormalities are rare but important to recognize because lowering of the pulmonary artery pressure by PDA ligation or closure of a VSD can be fatal if the ALCAPA is not noted. In utero, with equal pulmonary arterial and aortic pressures, satisfactory perfusion of the ALCAPA can occur. After birth, the pulmonary artery pressure falls, and left coronary artery perfusion decreases. Ischemia causes impaired ventricular function and myocardial infarcts and leads to left ventricular dilation. Papillary muscle dysfunction causes mitral regurgitation. Early coronary collateral development may prevent ongoing infarction.

Diagnosis and indications for intervention. ALCAPA is suspected in any infant with mitral regurgitation, ventricular dysfunction, or dilated cardiomyopathy. Infants present with low cardiac output and systemic heart failure. Feeding may also precipitate sudden death and angina in infants. Sudden death has also been described in older children. The ECG may reflect ischemic changes. The echocardiogram is usually diagnostic. However, because this diagnosis is often confused with dilated cardiomyopathy, there is an argument in favor of catheterizing all patients with dilated cardiomyopathy in whom the coronary artery anatomy cannot be clearly defined on echocardiography. Secondary findings of dilated cardiac chambers and segmental wall motion abnormalities, together with mitral regurgitation, prompt a search for an ALCAPA. Diagnosis of an ALCAPA is an indication for intervention.

Surgery. A degree of ventricular dysfunction is usually present. Preoperative inotropic support and optimization of hemodynamics may be required before surgical intervention. Severe cardiomyopathy rarely may necessitate cardiac transplantation. Current experience indicates that creation of a dual coronary system is safe and reproducible and offers the best opportunity for recovery of function. Operative considerations include optimal myocardial protection and prevention of left heart distention. Direct reimplantation of the ALCAPA into the ascending aorta is the procedure of choice (Fig. 113.48). Sometimes, limited mobility of the coronary artery precludes reimplantation, and a surgically created aorta–pulmonary artery–coronary artery tunnel is created; this is

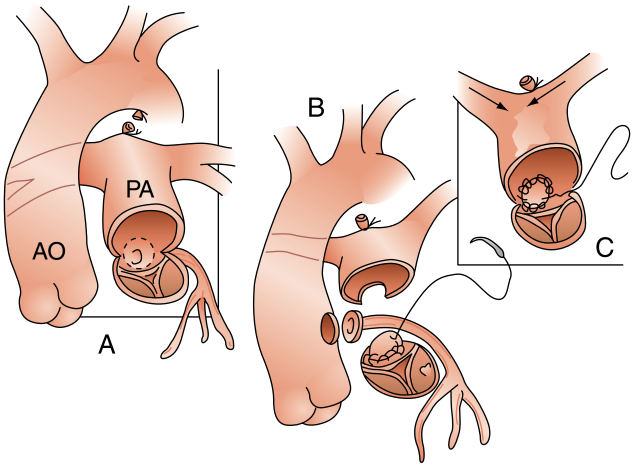

FIGURE 113.48 Direct reimplantation of anomalous left coronary artery arising from the pulmonary artery (ALCAPA). (A) Excision of ALCAPA from the pulmonary artery *(PA)*. (B) Aortic reimplantation of the coronary ostium into the aorta. (C) Reconstruction of the PA with autologous pericardium. *AO*, Aorta. (From Vouhe PR, Tamisier D, Sidi D, et al. Anomalous left coronary artery from the pulmonary artery: results of isolated aortic reimplantation. *Ann Thorac Surg*. 1992;54:621-626.)

known as the *Takeuchi procedure*. Ligation of the ALCAPA is not recommended.

Postoperative management is directed toward maintaining adequate coronary perfusion and cardiac output. Mechanical support of the heart may be temporarily required. Mitral regurgitation usually improves, and valve replacement is rarely necessary. Current intervention has a low operative mortality. Risks for mortality relate to preoperative ventricular dysfunction and cardiogenic shock. The Takeuchi repair is associated with tunnel complications such as obstruction, leak, aortic valve damage, and RVOTO in the long term.

Coronary Arteriovenous Fistula and Aneurysms

Isolated coronary artery fistula is more rare than ALCAPA. Drainage of coronary artery fistula is reported to terminate more commonly in the right side of the heart or pulmonary artery than in the left side of the heart. A shunt from the high-pressure coronary artery system into a low-pressure cardiac chamber may result in coronary steal and some degree of cardiac volume overload. Coronary artery aneurysms are associated with Kawasaki disease.

Diagnosis and indications for intervention. Presentation depends on the amount of functional compromise produced by the ischemia and volume overload. Echocardiography may be able to delineate the anomaly, but coronary angiography is diagnostic. Details of coronary anatomy are essential for determining intervention. Interventional catheterization is useful for the obliteration of fistulas and terminal aneurysms.

Surgery. If the lesion is not amenable to transcatheter intervention, surgery is indicated. Options include suture ligation without bypass, cardiopulmonary bypass, and aneurysmectomy with closure of the fistula. Early and late mortality rates are low. Risk factors for death and ventricular dysfunction relate to coronary artery insufficiency and infarction after fistula ligation or aneurysmectomy.[55]

Ebstein Anomaly of the Tricuspid Valve

Ebstein anomaly of the tricuspid valve is a rare defect in which the tricuspid valve attachments are displaced into the RV to varying degrees as a result of failure of delamination. Ebstein anomaly includes a spectrum of abnormalities involving a degree of displacement of the tricuspid valve, variable right ventricular size, and variable pulmonary outflow obstruction. Associated abnormalities are ASD, pulmonary atresia, and ccTGA. The posterior and septal leaflets of the tricuspid valve are variably displaced toward the apex of the RV, which results in an atrialized portion of the RV. The anterior leaflet remains large and sail-like. The major hemodynamic issue is tricuspid incompetence with decreased pulmonary blood flow and, if an ASD is present, right-to-left shunting, causing cyanosis. Long-standing tricuspid incompetence leads to volume overload of an abnormal RV. Variable pulmonary outflow tract obstruction limits effective pulmonary blood flow. If adequate pulmonary blood flow requires continued ductal patency, the need for neonatal intervention is almost certain.

Diagnosis and Intervention

The more severe forms of Ebstein anomaly manifest with cyanosis in infancy. Critically ill neonates tend to have a severe form of the disease, with a grossly inefficient RV compounded by the high pulmonary resistance of the neonate or by pulmonary valve atresia. The mortality rate in this group is high. Older patients present in heart failure and may have cyanosis. Supraventricular dysrhythmias and the preexcitation syndrome (Wolff-Parkinson-White syndrome) are associated with Ebstein anomaly. Echocardiography is diagnostic. Critically ill neonates have poor survival rates, and surgery is indicated only after stabilization with PGE1 and controlled ventilation. In older patients, cyanosis and heart failure are indications to intervene, although earlier intervention in asymptomatic patients, before excessive right ventricular dilation, is being more actively pursued.

Surgery

In critically ill neonates, after stabilization, palliation with a systemic-to-pulmonary artery shunt may be required. The Starnes operation has allowed salvage in previously hopeless cases. This operation consists of patch closure of the tricuspid orifice, atrial septectomy, and a systemic-to-pulmonary artery shunt.[56] In patients with less severe forms of this disease, tricuspid valve repair or replacement is also an option. Surgical techniques for the treatment of Ebstein anomaly have been evolving, and outcomes are improving for this challenging group of patients (Fig. 113.49).[57]

Mitral Valve Anomalies

Most abnormalities of the mitral valve are associated with other complex lesions (e.g., Shone complex). More commonly, mitral disease in children is inflammatory in nature—that is, rheumatic disease or infective endocarditis. It may also be associated with collagen vascular disease and Marfan syndrome.

Mitral Stenosis

Mitral stenosis is caused by obstruction at a supravalvular, valvular, or subvalvular level, singly or in combination. Supravalvular stenosis is caused by a ring of fibrous tissue above the annulus of the mitral valve or attached to the proximal leaflets. Valvular stenosis involves the leaflets, with commissural fusion occurring with or without hypoplasia of the valve ring. Hypoplasia of the mitral valve is often associated with left ventricular hypoplasia. Frequently, the leaflets and subvalvular apparatus are also dysplastic. Fusion of the leaflets can lead to an accessory orifice and produce mitral stenosis at a purely valvular level (so-called

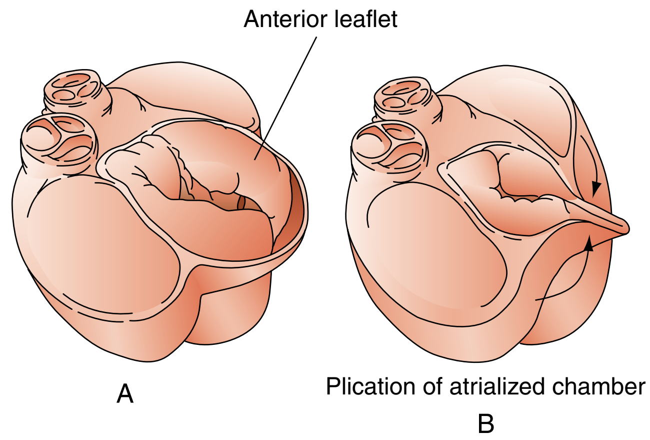

FIGURE 113.49 Repair of Ebstein malformation using the Carpentier method. (A) The anterior and posterior leaflets of the tricuspid valve are detached from the annulus. (B) The atrium is plicated, reducing the annular diameter. The detached leaflets are reattached to the annulus. (From Castaneda AR, Jonas RA, Mayer JE, et al. Ebstein's anomaly. In: *Cardiac Surgery of the Neonate and Infant*. Philadelphia: Saunders; 1994.)

double-orifice mitral valve). Three types of subvalvular stenosis have been recognized—parachute mitral valve, hammock valve, and absence of one or both papillary muscles. Mitral regurgitation is a result of secondary annular dilation, congenital isolated clefts of the valve, and prolapse of the leaflets from abnormal chordae or papillary muscle insertion.

Echocardiography is diagnostic. Intervention includes balloon valvuloplasty, particularly for selected forms of rheumatic mitral stenosis, and surgical intervention. Intervention is timed to avoid irreversible sequelae related to chronic volume overload or pulmonary hypertension. Surgical intervention is aimed at preserving the mitral valve, and valvuloplasty techniques have a valuable place in children. Prosthetic valves are the least desirable option. Bioprosthetic or tissue valves need to be avoided in children. Supraannular placement of the prosthesis may be necessary. Repeat placement is ensured.

SUMMARY

This chapter provides a basic overview of the major congenital cardiac lesions and a framework for the diagnosis and treatment of these conditions. For most patients, the diagnosis of CHD, whether surgically treated or not, carries lifelong implications. For patients with CHD presenting for noncardiac surgery, a thorough understanding of the patient's unique anatomy and physiology is mandatory when planning a rational management strategy. The reader is directed to several excellent texts on CHD for a more thorough review of each of the lesions reviewed in this chapter.

This text provides an excellent reference manual for understanding the complex anatomy of the heart. It contains color photographs and diagrams and is an invaluable resource for any student of cardiac surgery.

Bailey LL, Nehlsen-Cannarella SL, Doroshow RW, et al. Cardiac allotransplantation in newborns as therapy for hypoplastic left heart syndrome. *N Engl J Med*. 1986;315:949-951.

This classic reference describes the first report of cardiac transplantation in newborns with HLHS. Although limited in its applicability because of limited donor organs, neonatal cardiac transplantation has provided children born with HLHS a new option for survival.

Blalock A, Taussig HB. The surgical treatment of malformations of the heart in which there is pulmonary stenosis or pulmonary atresia. *JAMA*. 1945;128:189-202.

This landmark article describes the surgical procedure that initiated the era of elective cardiac surgery. The study reported the initial experience with palliative surgical treatment of patients with pulmonary stenosis or pulmonary atresia using the Blalock-Taussig shunt.

Fontan F, Baudet E. Surgical repair of tricuspid atresia. *Thorax*. 1971;26:240-248.

This article represents a milestone in the evolution of surgical management of patients with single-ventricle physiology. It described the first corrective operation for patients with tricuspid atresia. Although previous palliative procedures, provided by various systemic-to-pulmonary artery shunts, improved the clinical condition of patients, systemic blood was still a mixture of oxygenated and deoxygenated blood. The Fontan operation redirected SVC and IVC blood flow to the lungs so that only oxygenated blood returned to the heart and subsequently to the systemic circulation.

Kirklin JW, Dushane JW, Patrick RT, et al. Intracardiac surgery with the aid of a mechanical pump-oxygenator system (gibbon type): report of eight cases. *Mayo Clin Proc*. 1955;30:201-206.

This landmark article demonstrated that open repairs of congenital cardiac defects using mechanical pump oxygenator systems could be performed with minimal risk to patients.

Mustard W. Successful two-stage correction of transposition of the great vessels. *Surgery*. 1964;55:469-472.

This classic reference describes one of the initial surgical approaches to the treatment of d-TGA). Although the arterial switch operation is now the surgical treatment of choice for d-TGA, there are many adult patients with congenital heart disease who have been palliated with the Mustard operation. Understanding the operation and resulting physiology is critical to general surgery management strategies for noncardiac operations.

Norwood WI, Lang P, Casteneda AR, et al. Experience with operations for hypoplastic left heart syndrome. *J Thorac Cardiovasc Surg*. 1981;82:511-519.

In this landmark article, Norwood and colleagues reported the outcomes of what was then a new reconstructive surgical *technique to palliate newborns with hypoplastic left heart syndrome (HLHS). Until the Norwood operation, the only option for survival of patients with HLHS was cardiac transplantation. At most centers today, the Norwood operation is the primary mode of therapy for most neonates with HLHS.*

Sano S, Ishino K, Kawada M, et al. Right ventricle-pulmonary artery shunt in first-stage palliation of hypoplastic left heart syndrome. *J Thorac Cardiovasc Surg*. 2003;126:504-509.

This classic reference describes the right ventricle–to–pulmonary artery conduit used in the Norwood procedure. This novel procedure, named after the author, Sano, allowed for more hemodynamic stability postoperatively from the Norwood procedure and improved intrastage survival.

Senning A. Surgical correction of transposition of the great vessels. *Surgery*. 1959;45:966-980.

This classic reference describes the initial surgical approach to management of transposition of the great arteries (d-TGA). Although the arterial switch operation is currently the surgical treatment of choice for d-TGA, there are many adult patients with congenital heart disease in the community who have had the Senning operation. Understanding the operation and resulting physiology is critical to general surgery management strategies for noncardiac operations.

Starnes VA, Pitlick PT, Bernstein D, et al. Ebstein's anomaly appearing in the neonate. A new surgical approach. *J Thorac Cardiovasc Surg*. 1991;101:1082-1087.

This classic reference describes the first report of a new surgical approach to Ebstein anomaly in neonates. The procedure was named after the surgeon, Starnes. This approach has provided children born with severe Ebstein anomaly with a new option for survival.

Conclusion

ACUTE PULMONARY EMBOLISM

Epidemiology

Venous thromboembolism (VTE), defined as deep vein thrombosis (DVT) or pulmonary embolism (PE), is a relatively common disease, and it is believed to be the third most common cause of death from cardiovascular disease, after heart attack and stroke.[1] In the United States, VTE causes 100,000 to 180,000 deaths per year and is associated with significant cardiovascular and pulmonary morbidity.[2] The incidence of PE was estimated to be about 115 per 100,000 people in the United States,[3,4] whereas it is 39 per 100,000 in Hong Kong.[5] VTE incidence estimates are higher among Black populations and lower among Asian, Asian American, and Native American populations.[4–6] Despite an increased incidence of acute PE in the past decade, there has been a decline in mortality rates.[7] This may be related to earlier diagnosis and better risk-stratified treatment options as directed by a Pulmonary Embolism Response Team (PERT). In an epidemiologic study in Germany, the incidence of acute PE was 99 per 100,000 people/year over the 11-year period. The rate increased from 85 per 100,000 in 2005 to 109 per 100,000 in 2015. However, during the same period, in-hospital case mortality decreased from 20.4% to 13.9%.[8]

Pathology and Pathogenesis

VTE refers to both DVT and PE. PE occurs when the pulmonary artery is occluded by a thrombus or embolus that usually originates from the lower extremities. Partial or complete occlusion of calf or thigh veins reduces the velocity of flow in the more proximal femoral and iliac veins, enhancing the propagation of thrombus in the vein wall at the site of origin. The degree of organization within the thrombus varies, but recent clots are more likely to migrate than older thrombi that are more firmly attached to the vessel wall.

After acute PE, the patient may experience a wide range of symptoms, which can vary from sudden onset of pleuritic chest pain and dyspnea to a significant degree of right heart failure secondary to pulmonary obstruction and pulmonary hypertension (PH). In its most severe form it can cause hemodynamic collapse and death. The degree of PH and subsequent right heart dysfunction is likely multifactorial and related to the degree of mechanical occlusion of the pulmonary vascular bed, humoral factors released by the thrombus itself, and hypoxic pulmonary vascular spasm.[9,10]

Occluded vascular bed is the main cause of increased pulmonary vascular resistance (PVR) in acute PE. However, significant increases of PVR and the ensuing PH do not occur unless 30% or more of the pulmonary vascular bed is occluded.[11] In the absence of preexisting cardiopulmonary disease, the degree of PH is proportional to the degree of obstruction. However, a normal heart is not capable of maintaining high pulmonary pressures in an acute setting. Generally, the right heart is unable to maintain mean pulmonary artery pressure (mPAP) of over 40 mm Hg in an acute setting. This scenario typically occurs when 50% or more of the pulmonary vascular bed is occluded,[11] carrying an increased risk of developing acute right ventricle (RV) failure.[11] It is important to emphasize that clinicians should suspect the possibility of chronic thromboembolic pulmonary hypertension (CTEPH) when patients are able to maintain mPAP of over 40 mm Hg. Similarly, an episode of acute-on-chronic PE, or other non-VTE causes of PH, should be suspected when mPAP of over 40 mm Hg is maintained and tolerated.

However, simple mechanical obstruction of one or more pulmonary arteries may not entirely explain the often-devastating hemodynamic consequences. This hemodynamic reaction is a result of the interaction between the thrombus and the circulating platelets in the bloodstream, humoral factors (specifically serotonin and thromboxane A2), and the ensuing hypoxemia, all leading to further pulmonary vasoconstriction and bronchoconstriction, further worsening PVR after an episode of PE.[12] The main cause of hypoxemia in acute PE is the perfusion-ventilation mismatch that occurs in the open vasculature because increased compensatory blood flow in these nonobstructed vessels is mismatched with the subsequent bronchospasm.

Rudolf C. Virchow described the three major causes of thrombus formation in 1856, famously known as Virchow's triad: (1) venous stasis, (2) venous wall/endothelial injury, and (3) hypercoagulability.[13] Venous stasis may be caused by proximal mechanical obstruction, low cardiac output (CO), trauma, obesity, venous distention, increased viscosity, immobilization, frailty, pelvic tumors, pregnancy, congestive heart failure, or major surgery. Endothelial injury can be caused by trauma, smoking, and cancer. Hypercoagulability may include inherited hypercoagulable states, such as mutations in factor V Leiden, the prothrombin gene, and proteins C and S as well as antithrombin deficiency, antiphospholipid antibodies, and lupus anticoagulant.[14] Acquired risk factors include obesity, surgery, congestive heart failure, chronic lung disease, cerebrovascular accident, antiphospholipid antibody syndrome, drugs (estrogen preparations, oral contraceptives, steroids, etc.), and traveler's thrombosis caused by long-distance travel. If an underlying condition or risk factor leading to thrombus formation cannot be identified (i.e., idiopathic VTE), an occult malignancy should be ruled out. Arterial and venous thromboses, such as those in Trousseau syndrome, are seen in advanced malignancies.[15]

Natural History

Undiagnosed PE has a hospital mortality rate as high as 30%, compared with 8% when PE is diagnosed and treated appropriately.[14,16] Early diagnosis and appropriate treatments can greatly improve mortality. According to the International Cooperative Pulmonary Embolism Registry (ICOPER), out of 2454 patients with acute PEs, 7.9% had fatal PEs, with an all-cause mortality rate of 17.4% at 3 months. The mortality rate was significantly higher in hemodynamically unstable patients at 58.3%, compared with 15.1% in hemodynamically stable patients.[17]

When considering risk factors contributing to mortality, the rates are significantly higher in patients over the age of 70 and those with underlying cancer, congestive heart failure, and/or chronic obstructive pulmonary disease. Other poor prognostic signs and findings include systolic arterial hypotension, tachypnea, presence of RV hypokinesis on echocardiography,[17] free-floating thrombi in the RV,[18] patent foramen ovale,[19] and elevated cardiac troponin T levels.[20] According to the Japan VTE Treatment Registry (JAVA), cancer was the most common risk factor for VTE, at 27%. Inadequate anticoagulation using subtherapeutic levels of activated partial thromboplastin time (APTT), found in 37.6% of the patients, was the main culprit in this acute phase. Furthermore, the cumulative recurrence rate of VTE during warfarin treatment was 2.8 cases per 100 patients/year, but it was increased to 8.1 cases per 100 patients/year after warfarin treatment was stopped.[21] Recurrence rates were greater in patients with PE versus DVT, and among the survivors of PE, CTEPH developed in 2% to 4%.[2]

Clinical Presentation and Diagnosis

Clinical Presentation

Acute PE may present with varying degrees of signs and symptoms, and the clinical diagnosis is often missed. Most patients with acute PE present with dyspnea and chest pain. However, it can also present with tachypnea, cough, and/or hemoptysis. Examination may reveal tachycardia, rales, fever, and diaphoresis.[22] Hemodynamic instability is rare but an important consideration because it indicates central or extensive PE with severely reduced hemodynamic reserve. Syncope may also occur as a result of hemodynamic instability and RV dysfunction.[23]

The Geneva Score is one example of a clinical prediction model that can be used to determine the probability of PE (Table 114.1).[24] In addition to the presenting symptoms, the predisposing factors are also accounted for to predict the clinical probability of the disease. Such models are especially useful if PE is one of the differential diagnoses.

Laboratory Findings

Chest radiography (CXR) may show some subtle abnormalities, but its findings are not sensitive or specific for PE. Findings may include parenchymal infiltrate, atelectasis, or pleural effusion. A zone of hypovascularity or a wedge-sharped pleural-based density raises the suspicion for PE.

Similarly, electrocardiograms (ECGs) are not sensitive or specific for PE. Findings may include new right bundle branch block (RBBB), rightward shift of QRS axis, ST elevation of V1 and aVR, low amplitude QRS, premature atrial contraction (PAC), atrial fibrillation or atrial flutter, and T-wave inversion in V1 to V4.[25]

The arterial blood gas (ABG) may reveal hypoxemia (PaO$_2$ <80 mm Hg), hypocapnia, and high alveolar-arterial oxygen gradient (A-aDO$_2$ >20 Torr). However, blood gas analysis alone is not helpful in diagnosing PE because some patients may have a normal ABG with minimal ventilation-perfusion (V/Q) mismatch.[16]

TABLE 114.1 **Revised Geneva Score for Acute Pulmonary Embolism**

Risk Factors	
Age >65 years	1 point
Previous DVT or PE	3 points
Surgery (under general anesthesia) or fracture (of the lower limbs) within 1 month	2 points
Active malignant condition (solid or hematologic malignant condition, currently active or considered cured <1 year)	2 points
Symptoms	
Unilateral lower-limb pain	3 points
Hemoptysis	2 points
Clinical Signs	
Heart rate	
75–94 beats/minute	3 points
≧95 beats/minute	5 points
Pain on lower-limb deep venous palpation and unilateral edema	4 points
Clinical Probability	**Total**
Low	0–3 points
Intermediate	4–10 points
High	≧11 points

DVT, Deep vein thrombosis; *PE,* pulmonary embolism.

D-dimer is a protein fragment from the degradation of blood clots. D-dimer levels are elevated in plasma in the presence of acute thrombosis because of simultaneous activation of coagulation and fibrinolysis. The negative predictive value of D-dimer testing is high, and a normal D-dimer level renders acute PE or DVT unlikely. On the other hand, the positive predictive value of elevated D-dimer levels is low, and D-dimer testing is not useful for confirmation of PE.[26] D-dimer is also frequently elevated in older adult patients; in hospitalized patients; in patients with cancer, severe infection, or inflammatory disease; and during pregnancy.[27–29]

Although echocardiography is not highly sensitive or specific in the diagnosis of acute PE, it can nevertheless be extremely valuable.[30] The two most useful echocardiographic findings for diagnose of acute PE are RV enlargement and the McConnell sign. The McConnell sign is defined as RV free wall akinesis with sparing of the apex. On echocardiography, it appears as if the apex is bouncing up and down while the rest of the RV is still. The "D" sign may be present, which is the result of RV overload and shifting of the septum toward the left side of the heart.[31] The tricuspid annulus plane systolic excursion (TAPSE) and tricuspid regurgitation peak gradient (TRPG) are echocardiographic indicators of RV function and can help differentiate between submassive versus nonmassive PEs. In cases with RV dysfunction, the prognosis is worse.[32] Echocardiography is used not only as a screening method for PE but also for determining the severity of the disease and the subsequent treatment plan.

Imaging Findings

Multidetector computed tomographic pulmonary angiography (CTPA) is the method of choice for imaging the pulmonary vasculature in patients with suspected PE.[26] The Prospective Investigation on Pulmonary Embolism Diagnosis (PIOPED) II study observed a sensitivity of 83% and a specificity of 96% for CTPA in PE diagnosis. Fig. 114.1 shows examples of acute PE as seen on CTPA. In patients with a low or intermediate clinical probability of PE, a negative CTPA has a high (96%) negative predictive value for PE.[33] Furthermore, multidetector CTPA is more sensitive in detecting smaller PEs within the subsegmental pulmonary arteries compared with single-detector CTPA, increasing the rate of subsegmental PE diagnosis.[34]

With advancements in the diagnostic power of CTPA, use of lung scintigraphy in the acute setting has decreased. V/Q scans provide confirmatory evidence, but these studies may be less reliable in acute PE as opposed to the chronic setting. In general, normal V/Q scans essentially exclude the diagnosis of clinically significant PE. Because pulmonary scintigraphy does not require the use of a contrast agent, it remains useful for patients with contrast medium–induced anaphylaxis or those with severe renal dysfunction. It may also be preferred in patients of young age as well as pregnant females because the radiation dose is lower than that of CTPA.[35] In addition to the standard imaging just described, there are several more advanced imaging modalities that are now available; these include perfusion single-photon emission CT (SPECT) and V/Q SPECT with or without enhanced CT, but few outcome studies are available, with incomplete follow-up.[36]

Pulmonary angiography was historically the gold standard for the diagnosis or exclusion of acute PE, but as technology has improved, CTPA offers similar diagnostic accuracy.[37] Given the less invasive nature of CTPA and its wide and immediate availability in most centers, it has become the diagnostic imaging of choice. Furthermore, in acute PE, hemodynamic instability can be a contraindication for pulmonary angiography.

Magnetic resonance angiography demonstrates high specificity and sensitivity for proximal PE, but it has a limited sensitivity for more distal PE.[38] It can be performed noninvasively; however, in most institutions, it is not readily available in an acute setting.

Risk Assessment of Acute Pulmonary Embolism

Risk assessment of acute PE is important not only for establishing the correct treatment strategy but also for determining short- and long-term prognosis. Of the clinical scores integrating PE severity and comorbidity, the Pulmonary Embolism

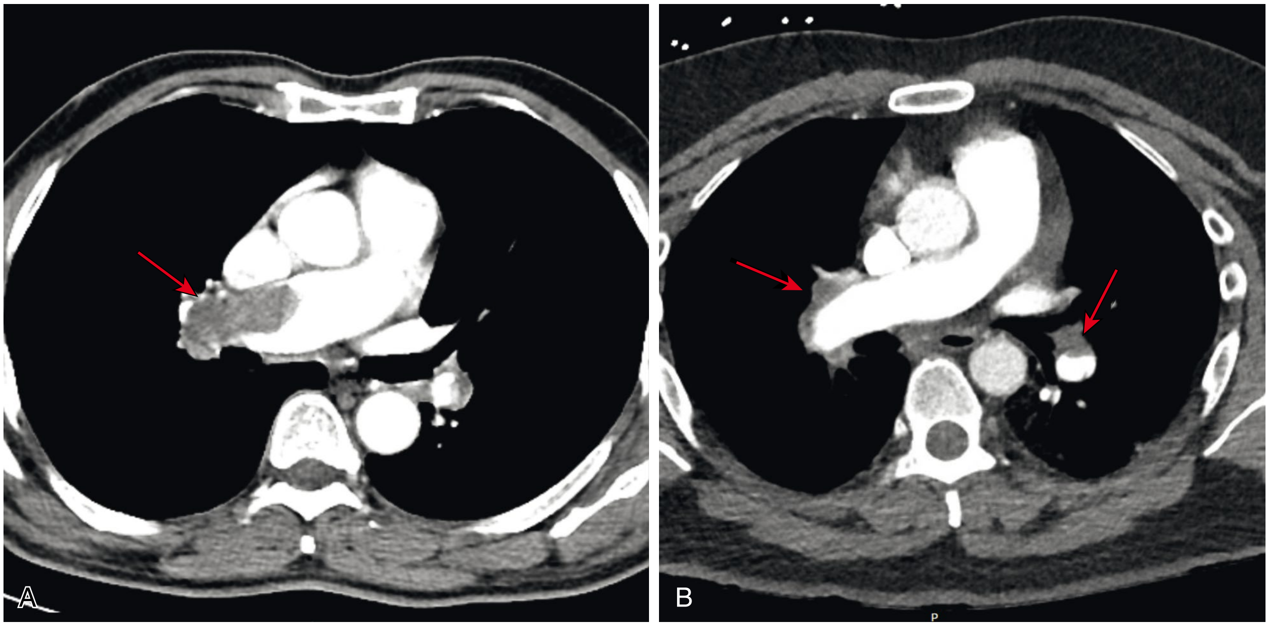

FIGURE 114.1 Computed tomography pulmonary angiography with axial sections showing (A) massive acute pulmonary embolism (PE) occluding right pulmonary artery *(arrow)* and (B) bilateral acute PE occluding right upper lobe and left interlobar arteries *(arrows).*

Severity Index (PESI) has been the most extensively validated to date.[39] The principal strength of the PESI lies in the reliable identification of patients at low risk for 30-day mortality (PESI classes I and II).[26] Given the complexity of the original PESI, a simplified version (sPESI) has also been developed and validated (Table 114.2).[40] RV dysfunction assessed by CT, echocardiography, or cardiac biomarkers is associated with an increased risk of mortality, even in patients with hemodynamically stable PE.[41] RV/left ventricle (LV) diameter ratio >1.0 and a TAPSE <15 mm on echocardiography also carry an unfavorable prognosis.[42] Similarly, elevated concentrations of troponin I or T and brain natriuretic peptide (BNP) are associated with unfavorable prognosis in acute PE.[43,44]

TABLE 114.2 Original Pulmonary Embolism Severity Index (PESI) and Simplified PESI (sPESI)

PREDICTORS	ORIGINAL VERSION	SIMPLIFIED VERSION
Age	Age in years	1 point (if age >80 years)
Male sex	+10 points	—
History of cancer	+30 points	1 point
History of heart failure	+10 points	1 point (combined into a single category of chronic cardiopulmonary disease)
History of chronic lung disease	+10 points	
Pulse ≧110/minute	+20 points	1 point
Systolic blood pressure <100 mm Hg	+30 points	1 point
Respiratory rate ≧30/minute (assessed with or without the administration of supplemental oxygen)	+20 points	—
Temperature <36°C	+20 points	—
Altered mental status (confusion, disorientation, or somnolence)	+60 points	—
Arterial oxygen saturation <90%	+20 points	1 point
Total point scores	30-day mortality risk	
Class I: ≦65 points	Very low (0%–1.6%)	0 points (low risk)
Class II: 66–85 points	Low (1.7%–3.5%)	
Class III: 86–105 points	Moderate (3.2%–7.1%)	≧1 point(s) (high risk)
Class IV: 106–125 points	High (4.0%–11.4%)	
Class V: >125 points	Very high (10.0%–24.5%)	

Note: For the original PESI, the total score for the patient is obtained by adding the patient's age in years to the points for each applicable predictor.
Modified from Konstantinides SV, Meyer G, Becattini C, et al. 2019 ESC guidelines for the diagnosis and management of acute pulmonary embolism developed in collaboration with the European Respiratory Society (ERS). *Eur Heart J.* 2020;41:543-603; Elias A, Mallett S, Daoud-Elias M, et al. Prognostic models in acute pulmonary embolism: a systematic review and meta-analysis. *BMJ Open.* 2016;6:e010324; Jiménez D, Aujesky D, Moores L, et al. Simplification of the Pulmonary Embolism Severity Index for prognostication in patients with acute symptomatic pulmonary embolism. *Arch Intern Med.* 2010;170:1383-1389.

The American Heart Association (AHA) classifies PE as massive, submassive, and low risk. *Massive* PE is truly life threatening and is defined as acute PE with sustained hypotension (systolic blood pressure less than 90 mm Hg for at least 15 minutes; inotropic support; and not due to a cause other than PE, such as arrhythmia, hypovolemia, sepsis, or LV dysfunction), pulselessness, or persistent profound bradycardia (heart rate below 40 beats/min with signs or symptoms of shock). *Submassive* PE is defined as acute PE without systemic hypotension (systolic blood pressure <90 mm Hg) but with either RV dysfunction or myocardial necrosis. RV dysfunction is categorized as the presence of at least one of the following: RV dilation (apical four-chamber RV diameter divided by LV diameter >0.9) or RV systolic dysfunction on echocardiography, RV dilation on CT (four-chamber RV diameter divided by LV diameter >0.9), elevation of BNP (>90 pg/mL), elevation of N-terminal pro-BNP (>500 pg/mL), or electrocardiographic changes (new complete or incomplete RBBB, anteroseptal ST elevation or depression, or anteroseptal T-wave inversion). Myocardial necrosis is defined as either one of the following: elevation of troponin I (>0.4 ng/mL) or elevation of troponin T (>0.1 ng/mL). *Low-risk* PE is defined as acute PE and the absence of the previously described clinical markers that would define massive or submassive PE.[45] The prognosis and recurrence rate of the disease differ significantly depending on presence of cardiac dysfunction.

The European Society of Cardiology (ESC) advocates a classification of severity in the form of high-risk, intermediate-high-risk, intermediate-low-risk, and low-risk groups in terms of early (in-hospital or 30-day) mortality.[26] Table 114.3 summarizes ESC risk classification.

Treatment

Respiratory and Circulatory Management

The mismatch between ventilation and perfusion is the main cause of hypoxemia of acute PE. Administration of supplemental oxygen is considered for the patients with Sao_2 <90%. Severe hypoxemia may be related to right-to-left shunting through a patent foramen ovale or atrial septal defect.[19] In cases of severe respiratory instability, further oxygenation techniques, including high-flow nasal cannula oxygen and mechanical ventilation, should also be considered.

Acute RV failure leading to low systemic CO is the leading cause of death in patients with high-risk acute PE. If the central venous pressure is low, volume loading using saline or lactated Ringer solution should be considered. Aggressive volume expansion should be avoided because it may worsen RV dilation and function. Central venous pressure can be assessed by echocardiographic imaging of the inferior vena cava (IVC). For patients in cardiogenic shock, norepinephrine can improve systemic hemodynamics by improving ventricular systolic contraction and coronary perfusion without causing a change in PVR. However, excessive vasoconstriction may worsen tissue perfusion. Dobutamine may be considered for patients with low cardiac index, but it may aggravate arterial hypotension if used alone without a vasopressor, especially if left heart failure is also present. Levosimendan may favorably affect RV-arterial uncoupling by combining RV inotropy and pulmonary vasodilation; however, it is still in phase III trial in the United States and is not FDA approved.[31] Vasodilators decrease pulmonary artery pressure (PAP) and PVR but may worsen systemic hypoperfusion because of their lack of

TABLE 114.3 The European Society of Cardiology's Classification of Severity in the Form of High, Intermediate (High and Low), and Low-Risk Groups in Terms of Early Mortality

		INDICATORS OF RISK			
EARLY MORTALITY RISK		HEMODYNAMIC INSTABILITY	CLINICAL PARAMETERS OF PE SEVERITY AND/OR COMORBIDITY: PESI CLASS III–V OR SPESI ≧1	RV DYSFUNCTION ON TTE OR CTPA	ELEVATED CARDIAC TROPONIN LEVELS
High		+	(+)	+	(+)
Intermediate	Intermediate-High	–	+	+	+
	Intermediate-Low	–	+	One (or none) positive	
Low		–	–	–	Assessment optional; if assessed, negative

Note: Hemodynamic instability means that at least one of the following is present: cardiac arrest, obstructive shock, or persistent hypotension. *CTPA,* Computed tomographic pulmonary angiography; *PE,* pulmonary embolism; *PESI,* Pulmonary Embolism Severity Index; *RV,* right ventricle; *sPESI,* simplified Pulmonary Embolism Severity Index; *TTE,* transthoracic echocardiogram.

specificity for the pulmonary artery. However, inhaled nitric oxide selectively dilates the pulmonary artery and may improve the hemodynamic status of patients with PE.[46]

The temporary use of mechanical circulatory support, commonly with venoarterial extracorporeal membrane oxygenation (VA ECMO) using peripheral vessel cannulation, may be helpful for hemodynamically unstable patients.[47] ECMO can be implemented outside the operating room. The femoral vein and artery are rapidly cannulated under sterile conditions using local anesthesia. The perfusion circuit consists of a small venous reservoir with intravenous access tubes, a centrifugal pump, and a membrane oxygenator. Blood from the venous system is collected from the right atrium (RA) using a cannula inserted through the femoral vein, and oxygenated blood is pumped through the femoral artery to the arterial system (Fig. 114.2). During ECMO, heparin is infused to maintain activated clotting times between 150 and 180 seconds. ECMO is useful as a bridge to decision or recovery while the patient is on anticoagulant therapy. It can also be used as a bridge to target therapy using catheter-directed fibrinolysis, percutaneous suction embolectomy, or other catheter-guided clot-retrieval devices as well as surgical embolectomy. ECMO can also be quite useful intraoperatively and postoperatively as a bridge to recovery.

FIGURE 114.2 A critically ill patient in an intensive care unit setting being supported on venoarterial extracorporeal membrane oxygenator (VA ECMO) circuit.

Percutaneous RV assist devices, such as Impella RP (Abiomed, Danvers, MA), can be used in patients with severe RV failure. It is authorized for treating acute PE only in emergencies associated with acute right heart failure or decompensation resulting from complications of coronavirus disease 2019 (COVID-19). However, in recent years, the device has been successfully used more frequently in patients with acute PE who may not be eligible for other conventional treatments. The device is a microaxial flow pump, which can be placed percutaneously, with the inflow placed within the IVC or RA and the outflow in the pulmonary trunk.[48]

Medical Therapy

Parenteral Anticoagulation

Anticoagulation is the first line of treatment for acute PE. The first and only randomized controlled trial (RCT) that compared anticoagulant therapy with no anticoagulant therapy in patients with symptomatic DVT or PE was in 1960, and it showed 5 deaths (26.3%) and 5 recurrences in 19 control untreated patients versus no deaths or fatal recurrences from acute PE in the 16 treated patients.[49] Therapeutic anticoagulation should be immediately given to patients with objectively confirmed PE and no contraindication to anticoagulation.

Furthermore, systemic anticoagulation is recommended for patients with high clinical suspicion of acute PE while awaiting studies to confirm the diagnosis, as long as there are no contraindications to therapy.[26,45,50] Subcutaneous low-molecular-weight heparin (LMWH), fondaparinux (Xa inhibitor), or intravenous unfractionated heparin (UFH) is usually used.

It is reported that fixed-dose LMWH is more effective and safer than adjusted-dose UFH for the initial treatment of VTE.[26] Compared with UFH, LMWH significantly reduced the incidence of thrombotic complications, the occurrence of major hemorrhage, and overall mortality.[51] Neither LMWH nor fondaparinux needs routine monitoring of anti-Xa levels. Local considerations, such as cost, availability, and familiarity of use, dictate the choice between fondaparinux and LMWH.[50] LMWH and fondaparinux are not cleared adequately in patients with renal impairment, whereas this is not a concern with UFH.[50]

UFH should be used in patients with overt hemodynamic instability or imminent hemodynamic decompensation in whom primary reperfusion treatment will be necessary.[26] For people with confirmed PE and hemodynamic instability, continuous UFH infusion should be offered and thrombolytic therapy considered.[52] UFH is recommended for patients in whom primary reperfusion is considered as well as for those with serious renal impairment (creatinine clearance [CrCl] <30 mL/min) or severe obesity.[53] Continuous intravenous injection is often started after initial injection to achieve and maintain an APTT prolongation of 1.5 to 2.5 times that corresponds to plasma heparin levels of 0.3 to 0.7 IU/mL anti-Xa activity.[54] The most significant complication of UFH is bleeding, and its incidence is reported to be 3% to 10%.[55,56] Because UFH has a short half-life of about 60 minutes, the effect is rapidly attenuated when intravenous administration is discontinued. However, in the case of a major or life-threatening bleeding complication, it is necessary to neutralize the effect of UFH with protamine sulfate. Rapid administration of protamine sulfate leads to a decrease in blood pressure, so it should be administered slowly over 10 minutes. Other complications of UFH include heparin-induced thrombocytopenia (HIT). As an alternative anticoagulant for the patient with HIT, argatroban can be chosen.[57]

Non–Vitamin K Antagonist Oral Anticoagulants

New oral anticoagulants (NOACs) or direct oral anticoagulants (DOACs) are a novel treatment option for acute VTE. NOACs are small molecules that directly inhibit one activated coagulation factor, which is thrombin for dabigatran and factor Xa for apixaban, edoxaban, and rivaroxaban. Owing to their predictable bioavailability and pharmacokinetics, NOACs can be given at fixed doses without routine laboratory monitoring.[26] A study in patients with atrial fibrillation showed that NOACs are an alternative for vitamin K antagonists (VKAs) to prevent stroke, and they have emerged as the preferred choice for anticoagulation.[58] Phase III trials on the treatment of acute VTE and those on extended treatment beyond the first 6 months demonstrated that NOACs have similar efficacy as VKAs in the treatment of acute symptomatic VTE, but they significantly reduce the risk of major bleeding.[59] Major bleeding occurred in 1.1% of NOAC-treated patients and 1.7% of VKA-treated patients.[26,59] Anticoagulant treatment using NOACs without preceding heparin or fondaparinux (single-drug approach) is possible. For low-risk PE patients, outpatient treatment with NOACs is also possible.[60] NOACs are contraindicated in patients with severe renal impairment (CrCl <15 mL/min), and its dose should be reduced appropriately for patients with renal impairment (CrCl <50 mL/min).[52]

Warfarin (Vitamin K Antagonist)

Warfarin has been the gold standard in oral anticoagulation for more than 50 years. When warfarin is used, anticoagulation with UFH, LMWH, or fondaparinux should be used as a bridge until a therapeutic international normalized ratio (INR) is achieved.[26] Individual responses to warfarin vary based on factors such as inpatient or outpatient status, age, genotype, concomitant medications, and comorbidities. The initial dose of warfarin may be 5 or 10 mg for younger patients. Initial doses <5 mg are appropriate for patients >75 years, the malnourished, those with liver disease or heart failure, those on medications known to inhibit warfarin's metabolism, and patients at high risk of hemorrhage. The INR should be measured daily, and warfarin doses should be adjusted to achieve an INR of 2 to 3. In patients with CrCl <30 mL/min, warfarin is the preferred anticoagulant. Warfarin is also preferred in patients with antiphospholipid antibody. DOACs and warfarin are contraindicated in pregnancy, and LMWH should be used.[61]

Systemic Thrombolysis

Thrombolysis in the treatment of PE was first described over 50 years ago. The general mechanism of fibrinolytic agents involves the activation of native plasminogen to plasmin, which hydrolyzes fibrin and leads to accelerated clot lysis. The goal of this process is to reduce thrombus burden, resulting in a more rapid relief of RV afterload and earlier hemodynamic improvement.[62] Thrombolytic therapy is associated with faster resolution of pulmonary embolic obstruction and improved right heart function compared with anticoagulation alone.[63] The greatest benefit is observed when treatment is initiated within 48 hours of symptom onset, and thrombolysis can still be useful in patients who have had symptoms for 6 to 14 days.[26,64] However, a meta-analysis of thrombolysis trials that included patients with high-risk PE found that compared with heparin, thrombolytic therapy was associated with a significant reduction of PE-related mortality and PE recurrence. Major hemorrhage and fatal or intracranial bleeding were significantly more frequent among patients receiving thrombolysis.[62] Systemic thrombolysis carries an estimated 20% risk of major hemorrhage, including a 3% to 5% risk of hemorrhagic stroke.[65] The dose-response relationship for systemic thrombolysis in acute PE remains unknown.[63] Therefore, systemic thrombolytic therapy should only be considered for people with massive PE associated with hemodynamic instability who do not have a high bleeding risk.[45,52] The absolute contraindications are history of hemorrhagic stroke or stroke of unknown origin; ischemic stroke in previous 6 months; central nervous system neoplasm; major trauma, surgery, or head injury in previous 3 weeks; bleeding diathesis; and active bleeding. Recombinant tissue-type plasminogen activator (rtPA), streptokinase, and urokinase are approved forms of therapy, but the accelerated intravenous administration (100 mg over 2 hours) of rtPA is preferable to prolonged infusions of streptokinase and urokinase.[26]

Percutaneous Interventions

Catheter-Directed Thrombolysis

According to the American College of Clinical Pharmacy (ACCP) guideline, in patients with acute PE who are treated with a thrombolytic agent, systemic thrombolytic therapy using a peripheral vein is preferred over catheter-directed thrombolysis (CDT). However, when expertise and resources are available, CDT may be preferred for patients with ongoing hypotension, those with high bleeding risk from systemic administration, those with failed systemic thrombolysis, and shock patients at risk of death before systemic thrombolysis can take effect (e.g., within hours).[45] A recent meta-analysis summarizing the outcomes with CDT for acute PE over the last decade showed an overall clinical success rate of 81.3%, a 30-day mortality rate of 8.0%, and a major bleeding rate of 6.7% for high-risk PE patients, compared with a clinical success rate of 97.5%, a 30-day mortality rate of 0%, and major bleeding rate of 1.4% for intermediate-risk PE.[66,67] Compared with systemic thrombolysis, in-hospital mortality and intracranial hemorrhage rates were lower for the CDT group; however, this came at a higher hospitalization cost.[68] The optimal dose of thrombolytic has not been clearly defined but is substantially lower (10%–25%) than the standard systemic dose.[69,70] The procedure is typically performed through right internal jugular access, with right heart catheterization (RHC), baseline hemodynamic measurements, and pulmonary angiography.

Catheter-Assisted Thrombus Removal

Although CDT has been proven useful, it is associated with higher bleeding risk and complications. Catheter-assisted thrombus removal (CATR) is a treatment strategy performed via a catheter-directed suction device and involves mechanical aspiration of the thrombus, with or without the use of thrombolytics. The bleeding rate varied in several studies, but the first meta-analysis on aspiration thrombectomy in acute PE showed that the rate of major bleeding was 4.98%.[71] Further studies and data are needed to evaluate the efficacy of this therapy.

Surgery: Pulmonary Embolectomy

The 2011 AHA guidelines indicate that it is reasonable to consider catheter embolectomy or surgical embolectomy for patients with massive PE who cannot receive fibrinolysis or those who remain unstable after fibrinolysis. They may also be considered for patients with submassive acute PE with poor prognosis (new hemodynamic instability, worsening respiratory failure, severe RV dysfunction, or major myocardial necrosis).[45] According to the 2019 ESC guidelines, the indications for surgical embolectomy areas follows: high-risk acute PE in patients who have contraindications to fibrinolytic treatment, ineffective thrombolysis, and intermediate-high-risk acute PE in patients with hemodynamic deterioration during anticoagulation therapy.[26] Coexisting RA and RV thrombus in acute PE is associated with an increased risk of death, and surgery should be considered.[72] In patients with RV overload, the migration of additional thrombus into the pulmonary circulation may result in a sudden hemodynamic collapse, and surgery may provide more favorable results.[48]

Although Frederick Trendelenburg first proposed the mechanism of direct thrombus removal from pulmonary arteries in 1908, the first successful surgery was reported by Kirschner in 1924, with survival of a few months. The results of this surgery had been disastrous until cardiopulmonary bypass (CPB) was established. Sabiston, Sharp, and Allison all made major contributions to the field, but Cooley reported the first successful case using CPB in 1961.[70]

The surgery is performed through a midline sternotomy incision. The ascending aorta and both vena cavae are cannulated after full heparinization, and CPB is initiated. It is often performed without aortic cross-clamping and cardioplegic cardiac arrest, but the procedure can also be performed with aortic cross-clamping and cold cardioplegia, particularly in patients with coexisting thrombi in the right heart cavities and in the presence of thrombi straddling the foramen ovale. In these cases, the heart may be electrically fibrillated or arrested with cold cardioplegic solution. Significant hypothermia may not be necessary because only a short period of complete bypass is needed. The main pulmonary artery is opened 1 to 2 cm downstream to the valve, and the incision is extended into the proximal left pulmonary artery. Forceps and suction catheters remove the clot from the left pulmonary artery and behind the aorta to the right pulmonary artery (RPA). The RPA can also be exposed and opened between the aorta and superior vena cava (SVC) to allow better exposure in the distal segments, if necessary. Unlike thrombi in chronic PE, relatively new, usually soft, rod-shaped red thrombi can be removed in acute PE. Although it is desirable to perform embolectomy as distal as possible, significant hemodynamic improvement can be achieved with removal of easily accessible large central thrombi. Fogarty balloon thrombectomy catheter is rarely used because of potential vessel wall injury to the distal pulmonary arteries by inserting it blindly. However, successful balloon catheter embolectomy under direct visual control by using a flexible choledochoscope has been reported.[73] In addition, acute PE may be complicated by presence of chronic thromboembolic PH (i.e., acute-on-chronic PE) (Fig. 114.3). In such a case, pulmonary thromboendarterectomy (PTE or PEA) is required. The procedure, described later in this chapter, is much more complex and requires significant expertise. Before proceeding with surgery, it is extremely important to ensure that the patent is not suffering from an episode of acute-on-chronic PE.

To prevent recurrent episodes of PE in patients with active DVT of large veins, a retrievable IVC filter may be considered during the perioperative period. IVC filters mechanically prevent venous clots from reaching the pulmonary circulation.

Postoperative Care and Complications

A systematic review of surgical embolectomy procedures determined that the most common postoperative complication was prolonged ventilation, seen in 33% of patients.[74] Surgical bleeding is also a common complication of the procedure, and it is worse in patients who receive preoperative thrombolytic therapy. Transfusion of clotting factors such as fresh frozen plasma and platelets may be helpful. Acute pulmonary hemorrhage may occur as a result of lung reperfusion injury rather than vessel wall perforation, but it can still be a challenging complication to deal with. In these patients, positive end-expiratory pressure (PEEP) and isolation of the active bleeding site using an endobronchial occlusion balloon can be helpful. Embolectomy usually improves hemodynamics promptly, but in patients with preoperative cardiopulmonary arrest, low CO syndrome may occur as a result of continued RV failure, likely related to ongoing RV ischemia. If hemodynamic instability continues despite the use of inotropic catecholamine support, ECMO should be considered (see earlier discussion). Perhaps the most devastating complication of acute

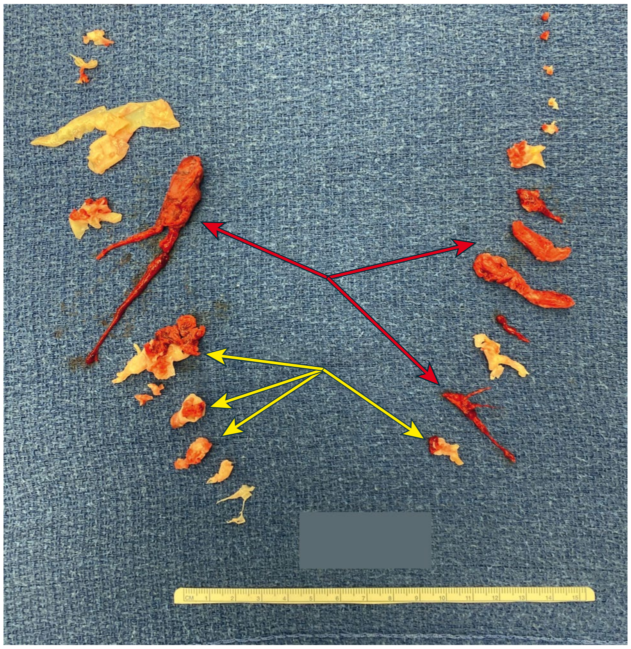

FIGURE 114.3 Specimen removed from the right and left pulmonary artery of a patient with mixed acute, subacute, and chronic pulmonary embolism. The *red arrows* point to the vessel with acute pulmonary emboli, and there is also clear evidence of organized chronic thrombus. *Yellow arrows* point to vessels with mixed disease.

pulmonary embolectomy in patients with cardiopulmonary arrest or prolonged shock is hypoxic encephalopathy. In such patients, full supportive measures using artificial ventilation, inotropic drugs, and ECMO are continued postoperatively until appropriate assessment of the neurologic status can be accomplished.

Outcomes of Pulmonary Embolectomy

The Society of Thoracic Surgery (STS) Adult Cardiac Surgery Database (ACSD) reports 1075 surgical embolectomies in North America between 2011 and 2015, with an overall mortality rate of 15.9%. The mortality rate varies widely, with 44.4% in patients with cardiac arrest before surgery, 23.7% in patients in shock but not requiring resuscitation, and 7.9% in patients without shock. Independent predictors of operative mortality included age, obesity, cardiogenic shock, preoperative arrest, chronic lung disease, unresponsive neurologic state, and prolonged CPB time.[75] Similar results were published in the Japanese Cardiovascular Surgery Database, where the overall operative mortality rate among 355 patients was 20.6%. In this report, the incidence of major adverse cardiovascular events (MACEs) was 27.3%. Independent risk factors for operative death were heart failure, poor LV function, and respiratory failure. Poor LV function, preoperative cardiopulmonary resuscitation (CPR), and respiratory failure were all independent risk factors for MACE.[76] There was a significant improvement in the systolic pulmonary artery pressure (sPAP), with a reduction in the mean sPAP from 57.8 mm Hg preoperatively to 31.3 mm Hg postoperatively. In-hospital mortality was 16%, and overall survival at 5 years was 73%.[74] Preoperative characteristics and risk factors remain the most crucial determinants of surgical outcomes.[48]

Chronic Treatment and Long-Term Outcomes for Acute Pulmonary Embolism

Oral anticoagulants are highly effective in preventing recurrent VTE. Patients with acute PE should receive 3 to 6 months of anticoagulant treatment. Extended duration of oral anticoagulant treatment reduces the risk for recurrent VTE, but this is partially offset by the risk of bleeding.[26] Compression stockings may be effective for patients with DVT to prevent postthrombotic syndrome, but routine use is not recommended.[77]

The highest risk factors for long-term recurrent VTE are active cancer, previous episodes of PE, or antiphospholipid antibody syndrome. These patients should receive indefinite anticoagulation. Cancer-associated thrombosis (CAT) is a condition in which relevance has been increasingly recognized for both physicians who deal with VTE and oncologists. The annual incidence of VTE in patients with cancer is currently estimated to be 0.5%, compared with 0.1% in the general population. Active cancer accounts for 20% of the overall incidence of VTE.[78] Risk of recurrent VTE should be weighed against the potential risk of bleeding in cancer patients when considering long-term anticoagulation therapy. It is conceivable that once cancer is cured, the risk for recurrence decreases, and anticoagulation can be stopped. Patients who are carriers of hereditary thrombophilia, such as antithrombin deficiency, protein C, or protein S as well as those with homozygous factor V Leiden, are also candidates for indefinite anticoagulant treatment.[26]

Long-term follow-up studies have consistently demonstrated that after an episode of acute PE, half of patients report functional limitations and/or decreased quality of life up to many years after the acute event. Incomplete thrombus resolution occurs in one-fourth to one-third of patients, and PAP and RV function remain abnormal despite adequate anticoagulant treatment in approximately 10% to 30% of patients, and 1% to 4% of patients are diagnosed with CTEPH.[79]

CHRONIC PULMONARY EMBOLISM AND CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION

Epidemiology

Chronic PE is caused by narrowing or occlusion of the pulmonary arteries as a result of an organized thrombus. *Chronic* is defined when abnormalities in the pulmonary blood flow distribution and pulmonary circulatory dynamics do not change, even after anticoagulation therapy, for 3 to 6 months or more.[80] Diagnostic criteria for CTEPH include mPAP greater than 20 mm Hg, pulmonary arterial wedge pressure less than 15 mm Hg, PVR greater than 3 Woods units, and evidence of chronic PE on imaging.

The exact incidence and prevalence of CTEPH remain undefined.[81,82] Multiple prospective and retrospective studies have shown that the incidence of CTEPH ranges between 1% and 5% after an acute episode of PE.[83] One meta-analysis reported an incidence of around 3% among patients surviving the acute PE event.[84] The incidence of CTEPH was higher in Asian patients than in European patients, with an incidence of 5% compared with 2%, respectively.[85] Risk factors for CTEPH are predominantly recurrent PE, unprovoked PE, older age, and large clot burden at the time of presentation.[83,84] However, 25% to 50% of patients with CTEPH do not have a documented history of acute PE, and the true incidence is thus underestimated. In addition, a large proportion of patients with residual symptoms after an acute PE event are not investigated. The overall incidence of CTEPH across the population was best investigated in Germany, where patients from three referral centers were prospectively followed. The researchers observed 392 new CTEPH diagnoses, yielding an incidence of 5.7 new cases per million inhabitants.[86]

Pathology and Pathophysiology

PH is divided into five distinct World Health Organization (WHO) groups, which are categorized according to pathophysiology, clinical presentation, and therapies. WHO group 4 is classified as PH resulting from pulmonary artery obstruction, of which there are two subdivisions: (1) CTEPH and (2) other pulmonary artery obstructions.[87] As indicated earlier, CTEPH is defined by mPAP greater than 20 mm Hg in the presence of organized, nonacute thromboemboli and altered vascular remodeling in the pulmonary artery.[88]

The exact pathophysiology of CTEPH is still unclear. Most cases of chronic pulmonary emboli are believed to originate from previous acute PE. In an international registry, a history of acute PE was reported by 75% of patients.[81] However, many individuals with chronic pulmonary thromboembolic disease are unaware of a past thromboembolic event and do not report a history of DVT.

The thromboembolic material in patients with CTEPH differs from that in acute PE. Microscopically, acute PE specimens contain predominantly fibrin, inflammatory cells, and red blood cells. In contrast, resected chronic thromboemboli are considerably more complex.[89] Current investigations in the pathogenesis of CTEPH suggest that it is unlikely that a single factor leads to the development of chronic PH after acute PE but rather that a host of clinical factors and alterations in the postthrombotic response leads to the formation of chronic intravascular scar and, ultimately, PH and RV dysfunction. Massive, idiopathic, and recurrent types of acute PE are suggested to be risk factors for development of CTEPH. Thrombophilic disorders, particularly antiphospholipid antibody syndrome and high coagulation factor VIII levels, were identified as a risk factor for CTEPH. CTEPH is also associated with other medical conditions, such as splenectomy, ventriculoatrial shunt, infected pacemaker leads, chronic indwelling catheters (e.g., ports and dialysis catheters), inflammatory bowel disease, systemic lupus erythematosus, malignancy, chronic venous ulcers, thyroid hormone replacement, and non-O blood group, among others.[89,90]

In CTEPH, the unresolved emboli within the pulmonary arteries undergo a series of changes. A fibrinolytic defect has been proposed to play a pathophysiologic role in the development of CTEPH. Fibrinolysis is a complicated process involving lysis of cross-linked fibrinogen through interactions between plasminogen, tissue plasminogen activator (t-PA), plasminogen activator inhibitor (PAI-1), and other regulatory proteins as well as interactions with the endothelium at the site of vessel injury. Reduced plasma fibrinolytic potential has been previously described as a risk factor for VTE, and some data suggest that this is true in CTEPH.[89] Factors such as the size and location of the emboli, the presence of multiple emboli, and underlying abnormalities in the clot-dissolving mechanisms can also contribute to incomplete resolution.

The chronic presence of the clots within the pulmonary arteries triggers inflammation and an immune response. This, in turn, leads to the proliferation of cells, remodeling of the blood vessel walls, and the formation of fibrous tissue that contracts the vessel. The remodeling narrows and obstructs the pulmonary arteries, increasing resistance to blood flow and causing elevated pulmonary arterial pressure. PH occurs after the remodeling and narrowing of the pulmonary arteries result in increased resistance to the blood flow from the RV to the lungs. The RV must work harder to pump blood against this increased resistance, leading to RV hypertrophy and, eventually, right heart failure.

In addition to the remodeling of larger pulmonary arteries, CTEPH also involves pathologic changes in small precapillary vessels, known as *distal arteriopathy.* These changes include the narrowing and obliteration of small arteries and arterioles, resembling the pathophysiology of Eisenmenger syndrome. Persistent PH from small-vessel disease after PTE remains the major cause of postoperative morbidity and mortality in CTEPH.[90]

Natural History

CTEPH is a severe and progressive disease, and most patients will die of progressive right heart failure without any treatment. The risk of death from right-sided heart failure in patients with undiagnosed or untreated CTEPH is correlated with PAP at diagnosis.[45] Riedel et al. reported that PH progressed in patients with an mPAP greater than 30 mm Hg, but no progress was observed in patients with a normal or borderline mean pulmonary arterial pressure. Among 13 patients, 9 died a mean of 28 months after the diagnosis of right heart failure. The severity of PH at the time of diagnosis inversely correlates with duration of survival. The 5-year survival rate was 30% for patients with mPAP greater than 40 mm Hg and only 10% for patients with PAP higher than 50 mm Hg.[91]

Clinical Presentation

Despite the importance of early diagnosis and intervention, recognizing CTEPH can be quite challenging because the clinical symptoms are nonspecific. The clinical picture often overlaps with other respiratory and cardiac conditions, contributing to the underdiagnosis of this condition, with varying signs and symptoms depending on the severity of the obstruction and right heart dysfunction.

Exertional dyspnea is the most common symptom. Patients may feel breathless even with minimal exertion. This dyspnea is often out of proportion to any abnormalities found on clinical examination.[45] Persistent fatigue and lack of energy are also commonly seen. Therefore, initially, dyspnea occurring only during exertion may be attributed to poor physical fitness, deconditioning, obesity, asthma, anxiety, or other more common causes of dyspnea on exertion, leading to delay in diagnosis.

As the disease progresses, additional symptoms may develop. Some patients with CTEPH may experience chest pain. Lightheadedness and syncope are also possible symptoms. Hemoptysis can occur in all forms of PH and may result from dilated vessels under increased intravascular pressures, but in CTEPH, hemoptysis is related to the development of large bronchial collaterals traversing to obstructed lung segments. Hemoptysis can also occur in the setting of infarcted lung parenchyma. Lower extremity edema, abdominal distention and early satiety, and right upper quadrant pain from liver capsular distention can occur as CTEPH progresses and are a direct result of right heart failure. Enlarged or prominent jugular veins in the neck may be easily visible.

Physical signs of PH are similar regardless of the underlying pathophysiology. Initially, the jugular venous pulse may exhibit a large A wave. As right heart failure progresses, the V wave becomes more prominent. The RV may be palpable near the lower left sternal border, and the closure of the pulmonary valve may be audible in the second intercostal space. With careful auscultation in the posterior lung regions, flow murmurs might be audible as flow accelerates past a tight stenosis in the pulmonary arteries. Advanced disease can lead to hypoxia and cyanosis.

As right heart failure develops, a right atrial gallop rhythm is often present, and tricuspid regurgitation develops. Because of the significant pressure gradient across the tricuspid valve in PH, the associated murmur is high-pitched and may not exhibit respiratory variation, which distinguishes it from murmurs associated with tricuspid valvular disease. A murmur of pulmonic regurgitation may also be detected.

Diagnosis

Patients presenting with unexplained dyspnea, exercise intolerance, or clinical evidence of right-sided heart failure, with or without prior history of symptomatic VTE, should be evaluated for PH, and CTEPH should be ruled out in all PH patients because it represents the only potentially curable form of PH. It is reasonable to evaluate patients with an echocardiogram 6 weeks after an acute PE to screen for persistent PH, which may help predict the development of CTEPH.[45] Because CTEPH is an important late sequela of acute PE, patients should be screened for radiologic signs of chronic lesions, especially if systolic PAP is >60 mm Hg by echocardiography at the initial presentation.[92] Follow-up is recommended at 3 months, and any impairment of physical capacity should be further evaluated.[26]

The diagnostic evaluation for CTEPH has three aims: (1) to establish the presence and severity of PH and resultant cardiac dysfunction; (2) to determine its cause; and (3) if thromboembolic disease is present, to determine the degree of obstruction and its concordance with the degree of PH to determine surgical candidacy.[45]

CXR is commonly performed, although it may be unrevealing even when there is significant PH. Enlargement of the central pulmonary arteries and RV may be observed. However, CXR is an important first step to narrow the differential diagnoses. Pulmonary function tests are necessary to evaluate dyspnea and are used to exclude the presence of obstructive airway or fibrotic lung disease. Single-breath diffusion capacity for carbon monoxide (DLCO) may be moderately reduced. Arterial blood oxygen levels may be normal even in the setting of significant PH, but most patients will experience a decline in $Pa{O_2}$ with exertion.[45] Echocardiography is used to provide objective evidence of PH. An estimate of PAP can be made by Doppler evaluation of the tricuspid regurgitant envelope.[93]

V/Q lung scan remains the most effective method to rule out CTEPH. It has 96% to 97% sensitivity and 90% to 95% specificity for the diagnosis.[94] In most patients with primary PH, the lung scan appears relatively normal, whereas in CTEPH, it shows nonuniform perfusion patterns that signify perfusion-ventilation mismatched areas. If subsegmental or larger perfusion defects are detected on the scan, pulmonary angiography is appropriate to confirm or rule out thromboembolic disease.

To confirm the diagnosis of CTEPH, RHC and contrast-enhanced CT angiography with multiplane reconstruction or conventional pulmonary angiography are needed. RHC establishes the severity of PH, which, by definition, requires an mPAP of over 20 mm Hg and a PVR >3 Wood units at rest. It also assesses right- and left-sided heart filling pressures. Measurement of oxygen saturations in the SVC and IVC, right-sided chambers, and pulmonary artery may document previously undetected left-to-right shunting.[45] Mixed venous saturation can also be used for Fick CO calculation because CO measured by the thermodilution method may be inaccurate depending on the degree of tricuspid regurgitation. For older patients, coronary angiography and left heart catheterization provide additional but important information for those at risk of coronary artery or valvular disease and those with diastolic LV dysfunction. These are necessary for the preoperative risk assessment of patients deemed candidates for pulmonary thromboendarterectomy (PTE) and to determine whether concomitant coronary artery bypass graft or valve surgery needs to be undertaken simultaneously.[95]

Pulmonary angiography remains the gold standard for diagnosing chronic pulmonary thromboembolism. Selective pulmonary angiography with digital subtraction is used to precisely display the peripheral regions of the pulmonary circulation and provides dynamic imaging of perfusion.[96] It can yield high-value information about the level of obstruction, the degree of disease, the status of more distal vessels, and any evidence of significant distal arteriopathy, all crucial for surgical planning. In angiographic imaging, thrombi appear as unusual filling defects, pouches, webs, or bands or as completely thrombosed vessels that may resemble congenital absence of a vessel.[45] Distal vessels exhibit the characteristic tapering and pruning associated with PH as a result of vessel wall thickening and proximal vessel dilation.

CTPA provides additional information and may serve as an alternative if performed with thin slices of 0.5 to 1 mm and coronal and sagittal reconstructions using 1-mm slices. The pulmonary artery branches are contracted by the organized thromboembolic material; therefore, slices of 0.5 to 1 mm are essential to adequately assess subsegmental branches. Disease located in the main, lobar, and segmental branches is amenable to surgical resection. Other perfusion studies, such as dual-energy CT or MRI, have theoretical advantages, but restricted availability and incomplete validation are important limitations.[97]

Some patients may present with normal pulmonary hemodynamics at rest despite symptomatic disease. If other causes of exercise limitation are excluded, these patients are considered as having chronic thromboembolic pulmonary disease without PH (CTEPD without PH), also referred to as *chronic thromboembolic disease* (CTED). These patients present with important symptomatology impairing their quality of life despite the lack of PH at rest. Their assessment therefore generally requires RHC with exercise and cardiopulmonary exercise testing (CPET). Identification of patients with CTED, who may have an indication for surgical or interventional treatment, requires particular expertise.[26]

Treatment

Surgery: Pulmonary Thromboendarterectomy/Pulmonary Endarterectomy

PTE, also known as *pulmonary endarterectomy* (PEA), is the treatment of choice and a potentially curative treatment for CTEPH. PEA was pioneered at the University of California, San Diego (UC San Diego), in which around 200 PEA procedures are now performed every year.[98,99] Around 0.9 PEA procedures per million population are performed annually in the United States and around 1.7 per million population in Europe,[99] representing a steady increase over the past decade as surgical expertise has improved and the number of expert centers has increased worldwide. Inserting an IVC device before endarterectomy has been abandoned at the leading surgical centers because IVC filter placement before surgery did not influence long-term survival.[88]

Although the fundamental techniques of PTE surgery are similar to those of other open-heart operations requiring profound hypothermia and periods of circulatory arrest, there are certain guiding principles for this procedure.[100] Median sternotomy, CPB, deep hypothermic circulatory arrest (DHCA), identification and dissection in the appropriate plane, and a complete endarterectomy are the principles of this procedure. The disease, and therefore its surgical removal, is almost always bilateral, although the volume of disease may vary significantly between the two lungs. Despite some recent experience with minimally invasive PTE surgery through mini–anterior thoracotomy incisions, the preferred approach to both pulmonary arteries is through a median sternotomy incision.

Exceptional visibility of the pulmonary vasculature is required to identify the endarterectomy plane and then to follow it deep into the subsegmental branches.[100,101] Because of the copious bronchial blood flow usually present in these patients, periods of DHCA are necessary to ensure perfect visibility. It should be emphasized that although endarterectomy is possible without DHCA, a complete endarterectomy is not. A large, randomized study from the Papworth group at Cambridge indicated inferior visualization and less complete endarterectomy in the low-flow non-DHCA patients, requiring intraoperative crossover to the DHCA group.[102] There was no statistically significant difference in cognitive function postoperatively, although the DHCA group had somewhat better outcomes. The DHCA periods are typically limited to 20 minutes, with restoration of flow between each arrest. With experience, the endarterectomy can usually be performed with a single period of DHCA on each side. A true endarterectomy in the plane of intima and media must be accomplished, and all fibrotic material must be removed. It is essential to appreciate that the removal of visible proximal thrombus is largely incidental to this operation.

Operative Techniques
